In the capital town of every state in Mexico there is a centre of the Secretaría de Obras Públicas (Secretary of Public Works). Its director is responsible for all public works carried out by the federal government in that state. In each centre there is a senior resident engineer who is in charge of the construction of rural roads[3]. Working for him is a team of resident engineers each located in a different region of the state. Each resident engineer has a team of engineers, surveyors, administrative personnel and supervisory staff. The exact number of his staff depends upon the number of roads being planned or constructed. The supervisory staff consists of supervisors and foremen. Supervisors are in charge of 3 to 5 foremen, whilst each foreman is in charge of 30 to 60 men.

The central headquarters of the programme is located in Mexico City in the Secretaría de Obras Públicas (SOP). A special unit has been set up to supervise the programme (Dirección General de Caminos Rurales). This unit consists of four main departments. These are:

Department of Works — responsible for monitoring the progress and cost of the programme and advising when action is necessary.

Department of Programming — responsible for preparing the budget and allocating funds to the SOP centres in the various states.

Technical Department — responsible for supervision of the technical aspects of the programme. This includes drawing up guidelines on technical specifications, cost estimates for labour, materials, equipment, etc. and productivity standards. It also collects data from the field in order to update these guidelines.

Department of Research and Special Studies — responsible for carrying out special studies on technical and economic aspects of the programme. In addition there is what is termed a promotion branch which is responsible for giving advice and assistance to the resident engineers in the field as regards the promotion within local communities of road-building activities.

This is necessary because the programme is dependent upon, and derives from, the willingness of local communities to become involved in road construction.

In the first instance a community will request that a road be built or upgraded. One of the resident engineer's staff then visits the community, assesses the situation and collects data pertaining to the number of households, agricultural production, social services, etc. If a decision is then taken to meet the community's request the official returns and explains that it is their responsibility to build and maintain the road. To this end a committee is elected which represents the community in its dealings with the resident engineer's office. A memorandum of understanding is drawn up in which the obligations of the two parties are clearly spelled out. Thus the committee undertakes to provide the necessary manpower; the free use of borrow pits and the right of way for the road. The DGCR undertakes to provide technical assistance, payment for the labourers, construction materials, hand tools, equipment and transport.

Two points are worth mentioning here. First, the system is designed to ensure the involvement of the community in the construction of the road, which it is hoped will guarantee its maintenance. Second, the DGCR has no official relations with the labourers except in terms of supervising the construction operations. The workers are paid by the committee and all labour relations are dealt with by them. The labourers therefore are not in any way employees of the Government. In a programme as large as this one decentralisation of administrative responsibility presents major problems of accounting and planning. To help to cope with these problems each SOP centre has a computer which is used to plan and control the financial disbursements of the programme. In turn the information from all the SOP centres is fed to the main computing centre at SOP headquarters which allows the Department of Works and Department of Programming to monitor and allocate the financial resources.

2. **Technical aspects**

2.1 *Design*

It was assumed that the traffic volume on the roads to be

constructed would be less than 50 vehicles/day. The roads were therefore designed to a design speed of only 20 – 30 kms per hour. This permits the use of radius of curvature as little as 15 – 20 m and maximum over-all gradient of 12 per cent.

The roads are designed for one-way traffic flow. The total formation width is 4.6 m with a 4.0 m wide, 15 cms deep gravel pavement. Every 500 m a 10 m stretch is widened to 6.0 m to allow vehicles to pass.

On simple rural roads, drainage is particularly important. This has been appreciated in the programme and special attention is given to it. The formation is crowned with a cross-fall of 4 per cent. Side drains of 1 m width and 1:3 side slopes are constructed. These have a minimum gradient of 0.5 per cent and where the gradient exceeds 6 per cent they are protected with a layer of hard pitched stone. On sloping ground catch drains are placed on the high side of the road to discharge run-off water before it reaches the road. Various culvert designs have been introduced but the most effective has proved to be corruged steel pipe.

To the extent possible, rivers and streams have been traversed by means of masonry fords. Where bridges have been necessary they were initially constructed as masonry arches. Recently however masonry pillars and reinforced concrete superstructure have been introduced. One interesting aspect has been the use of cobblestone roads where the gradient was unavoidably greater than 12 per cent.

2.2 *Construction*

Prior to construction work commencing the resident engineer and his staff prepare a simple bill of quantities which specifies the amount of work to be carried out in each of the major activities. This is then used to plan the work in terms of duration and resource requirements. This is possible because the reporting system incorporated into the programme provides detailed information on labour and equipment productivity under various climatic, topographical and soil conditions.

The resident engineer's team then sets out the centre line of the road. Tasks for each of the major activities are then fixed. These tasks generally cover a 3 to 4-day period. Each foreman,

who is in charge of 30 to 40 labourers, is briefed regarding the task levels set and any particular points that need attention. In turn he assigns his labourers to the various tasks.

Site clearance and top soil removal is almost always carried out by manual methods except (in the case of site clearance) when the vegetation is extremely dense.

The roads are designed and aligned to minimise cut and fill operations and to ensure that, in general, the excavated material for side drains and culverts can be used directly to form the basic road formation. Thus the material from ditching and sloping is used for spreading on the formation. This means that these operations can be carried out effectively by labour-intensive methods.

Where bulk excavation is unavoidable it has been found that labour-intensive methods are effective as long as the total volume does not exceed 2,500 m^3 per kilometre[4]. Where this figure is exceeded equipment is used. This is often operated by small contractors who are paid a fixed sum related to the type of soil being excavated.

Gravel for the pavement is obtained from borrow pits. Excavation and loading of the gravel is carried out either by labour or equipment depending on location, material and loading conditions. Dump trucks are used for hauling the material. Spreading and laying is carried out entirely by hand.

2.3 *Tools*

Each labourer is provided with a shovel and a pick-axe. Other hand tools such as crowbars, axes, hammers, etc. are distributed according to the type of activities being executed. The tools are produced in Mexico and their quality is very reasonable. For haul distances of up to 100 m wheelbarrows are used. The wheelbarrows used have a capacity of 0.07 to 0.09 m^3 and have massive rubber tyres.

2.4 *Recruitment and remuneration*

The community itself recruits the labour to work on the roads. Each labourer is guaranteed a minimum of two week's work. (In fact during the period 1971-75 53 per cent of the workers were employed for less than one month, 21 per cent for one to three months and 26 per cent for more than three

months.) In general the community committee attempts to ensure that all those who wish to work are given some employment.

Payment is usually at the level of the minimum rural wage, with one paid rest day per week. During the period 1972-75 the minimum rural wage rose from 25.38 pesos ($2) in 1972 to 40.89 pesos ($3.27) in 1975. The present rate of remuneration is approximately 70 pesos per day ($3.1). The actual direct cost of labour is a factor of 1.167 greater per day owing to payment for one rest day per week.

2.5 *General*

Some general indications can be given of the 64,000 kms of road already constructed under the programme. Only 14 per cent of the roads are in fact new roads, the great majority being improvements to the alignment, width, drainage and surfacing of existing tracks. The average length of the roads constructed is 10 kms and average construction period 9½ months.

The topography in which the roads have been constructed was classified in three categories, i.e. plain, hilly and mountainous[5]. Only 7.5 per cent of the roads were constructed in mountainous terrain, the rest being equally distributed between plain and hilly terrain.

The type of soil was classified into three types: soft, firm and hard. Nearly 60 per cent of the soils encountered were firm, 35 per cent soft and the remainder were hard. The vegetation through which the roads were constructed was generally (50 per cent) medium in density, a further 40 per cent was very light, whilst 10 per cent of the roads were constructed through jungle or forest.

2.6 *Selection of roads*

With such a large programme of road construction it was necessary to develop certain criteria of selection.

It was decided to concentrate road-building efforts on those communities of 500 – 2,500 population of which 65 per cent had no means of communication. This would provide access to the major part of 12 million people mentioned previously.

An initial, broad, identification was made to decide which

states in the country should be given priority. The criteria used for this broad selection were:

a) level of rural income;
b) number of localities between 300 and 800 inhabitants;
c) metres of constructed road per square kilometre of land surface;
d) metres of constructed road per 1,000 inhabitants;
e) number of vehicles per 1,000 inhabitants.

Actual project selection within each state was carried out based on certain specific criteria which related to maximising the "combined utility of the road". This was measured in terms of:

a) number of localities served by the road;
b) potential agricultural development;
c) permanent employment generated by construction of the road;
d) general socio-economic level;
e) zone of influence of the road.

The selection was qualified by such factors as budget restrictions, availability of labour, duration of construction and the technical difficulty of construction.

3. **Achievements**

3.1 *General*

During the five-year period 1971 – 75, 64,000 kms of road have been built at a total cost of 4,596 million pesos ($368 million). That is an average cost of $5,750 per kilometre. The total length of roads built under the programme amounts to 35 per cent of the length of the current road network in Mexico. In all, 6,174 communities with a total population of some 6 million have been provided with access. At its peak in 1973 the programme was providing temporary employment of 105,000 jobs per month. A rough calculation based on the time (relatively short) that workers spent on road construction suggests that over 1.5 million people were provided with temporary employment during the five-year period up to 1975.

3.2 *Output*

The actual construction output has varied considerably over

the five years 1971 – 75 as shown below:

Year	Output (kms)
1971	3 500
1972	11 000
1973	28 500
1974	10 500
1975	10 500
Total	64 000

A weighted average of the programmes indicates that 1,700 man-days per kilometre were used.

Detailed figures of labour productivity for various activities are shown in table 1 and a breakdown of the average quantity of work per kilometre is given in table 2.

Table 1. Labour productivity

Operation	Soil type	Output (m^3/man-day)
Cut to fill	Soft	4.5
	Firm	3.0
	Hard	1.2
Simple excavations	Soft	5.0
	Firm	3.0
	Hard	1.2
Spreading	All	15.0

Table 2. Average quantity of material per kilometre constructed

Operation	Average quantity per kilometre	
	Improved track	New road
Clearing	0.3 hectares	1 hectare
Excavation	1 670 m^3	2 800 m^3
Fill	1 313 m^3	1 415 m^3
Gravel	710 m^3	815 m^3

3.3 *Costs*

During the period 1972 – 74, for which a detailed analysis

has been carried out, the average direct costs for improvement of an existing track was 65,600 pesos per kilometre ($5,250) and for a new road 106,885 pesos per kilometre ($8,550).

For the bulk of the roads, which were improved tracks, the breakdown of costs was as follows:

Wages	60%
Materials	12%
Tools	4.5%
Services[6]	20%
Site supervision	3.5%

The cost and breakdown does not include the cost of central administration and headquarters which, in the case of the Mexican programme, is likely to have been quite considerable.

During this period (1972–74) the average minimum daily wage was 41 pesos. An analysis of the costs in 1975 shows[7] that the direct costs per kilometre for an improved track had risen to 93,500 pesos ($7,500).

Over-all it is estimated that of the direct cost 50 per cent is spent on earthworks, 3 per cent on drainage and 3 per cent on the gravelling operation.

A comparison was made of the costs of constructing an improved track by equipment-intensive methods under prevailing Mexican conditions[8]. This suggested that, even at market prices, there was little difference between labour and equipment even though the duration of construction for the equipment-intensive techniques was considerably less. It is worth noting that the on-site overheads for the equipment-intensive method (a total of 23.5 per cent of the total direct cost in the case of labour-based methods) was 33 per cent of the total direct cost.

3.4 *Employment*

The actual level of direct employment created is difficult to quantify as at least half of the workers were employed for less than a month. From the available figures[9] it is possible to suggest (i) that over 1.5 million people were provided with employment as a direct result of the road construction programme; (ii) during the period 1972–74 over 4 million man-months of employment were created.

Employment created using labour-based methods was five times that which could have been expected using equipment

and, as we have seen above, for the same investment cost.

Van Ginneken[10] has estimated that of the 5 million paid economically active persons in agriculture as many as 4 million are employed for less than 150 days a year. This should be seen in relation to the structure of agricultural employment which is basically of four types. The day-labourer having little or no land who hires himself out for work through the year; the co-operative farmer whose demand for employment depends upon the distribution of crop land; the small farmer (having less than five hectares) whose subsistence farming is often augmented by working as a day-labourer; large farmers. Employment in the programme was drawn from the first three. We can see therefore that even if a labourer works for only one month on the road he is, at the most conservative estimate, increasing his annual employment by 20 per cent, and consequently his earnings.

A sample survey which formed part of the work of the DGCR showed that three-quarters of the labourers working on the road had access to land; however, the average size of plot was only 2.9 hectares. This is extremely small when it is appreciated that the average family size was 6.3 and of the total family, an average of 3.6 were available for work. In over 90 per cent of the families all or part of the family labour force was available for work (i.e. unemployed or underemployed).

The average annual income of the families studied was approximately 7,000 pesos[11] which amounts to an annual income per economically active person of 2,000 pesos. One month's employment on the programme therefore amounted to an increase of 50 per cent in individual income or 15 per cent of family income.

A micro survey carried out by DGCR suggested that it was the day-labourers who benefited most from the programme whilst those who had land (not surprisingly) and the totally unemployed (surprisingly) benefited much less.

4. **Socio-economic impact**

Up to 1975 the programme had provided access to over 6,000 communities. A sample survey of these communities showed that:

a) for 70 per cent of them the only previous means of communication was on foot or by horse;

b) for the great majority the time taken to reach the nearest town was at least one hour and generally more than three hours;

c) 37 per cent lacked all types of services, 70 per cent had no potable water, 60 per cent no electricity, 60 per cent no school of any description, 90 per cent no medical service.

The survey also showed that over 90 per cent of the wages earned by workers on the programme was spent on consumption items.

The direct socio-economic impact of the construction of the roads was therefore an increase, in most cases a substantial increase, in family income. Unfortunately, because of the existing lack of facilities and the economic system this income was generally not spent in the communities but in towns to the merchants who supply basic commodities. The addition of funds to the community did not produce an increase in the local production of consumer goods. It is fair to add that this would only come about if complementary rural development activities took place at the same time as the road construction. Furthermore, the DGCR found that the improved communication provided by the roads tended to reinforce the existing economic structure. The richer members of the communities took advantage of the access provided whilst the poorer members, because of their lack of income, derived very little benefit from the access. Thus a richer family would now have access to fertiliser which they could afford and thus increase the quality and quantity of crops produced. The income derived by the poorest, though relatively substantial, was only used to increase consumption, partially because the previous consumption was so low and partly because of the class structure which did not allow them to break out of their subsistence economy. Thus the additional income provided the means whereby the basic needs of clothing, food and shelter could be obtained but were not sufficient to provide a basis for a continuing improvement in the people's economic condition. In this regard the survey found that the least impact occurred when the class structure was particularly rigid and land ownership vested in the hands of a few.

5. **Summary**

The programme is probably the largest of its kind presently in

operation. It has indicated clearly that even in economies where the agricultural wage rate is as high as $2.5, labour-based methods can be effective. However, it also shows that these methods require very detailed planning, organisation and management.

The detailed studies carried out by the DGCR have also shown that for a programme of rural road construction to be truly effective in the long term it must be accompanied by complementary rural development activities. If not then improvements to the standard of living of the mass of the population are unlikely to be achieved.

Notes and references

[1] This chapter is based on the various publications of the Secretaría de Obras Públicas, Mexico, related to this programme, in particular Secretaría de Obras Públicas, *Caminos y de Mano de Obra*, Mexico 1977.

[2] Defined as having no year-round access to a truckable road.

[3] It is interesting to compare this system with the RARP in Kenya where the RAR engineers are not part of the Provincial Engineers Organisation but report directly to the Central Headquarters.

[4] A similar conclusion has been reached from the Kenyan RARP.

[5] The classification was designated if more than 60 per cent of the road was in one type of terrain.

[6] This is principally transportation costs.

[11] This implies a per capita income of 1,100 pesos which should be compared with the *national* per capita income at the time of the survey of 11,000 pesos.

CHAPTER 7. THE SELF-HELP APPROACH: AFGHANISTAN

by G. Glaister

1. Introduction

This chapter describes a major programme of labour-based construction in Afghanistan. Unlike the programmes in Kenya, Philippines, India and Mexico referred to elsewhere, this programme is based on the principle of self-help, that is, the workers donate their services free or for the provision of food. Nevertheless the objective is not primarily the generation of employment but the development of rural infrastructure.

In Afghanistan there are two major agencies engaged in the construction and maintenance of roads. These are:

a) the Ministry of Public Works;

b) the Rural Development Department.

The former is responsible for primary and secondary roads and the latter for tertiary roads. In this context primary roads are defined as those connecting the provincial capitals with the centre (Kabul) and with the major international border crossing points and points of entry. Secondary roads are defined as those connecting the district capitals with the provincial capitals either directly or via the primary road system. Tertiary roads are defined as those connecting villages and other centres of production or marketing with the primary and secondary road systems.

The construction of the primary road system is well advanced and of the 27 provincial capitals, 17 are served by asphalt or concrete, two-lane, all-weather roads, 4 are served by good quality all-weather gravel roads and the other 6 by lower-grade earth or gravel roads which may be impassable in the wet season because of high water levels.

The secondary road system is much less developed and all-weather secondary roads are the exception. The bulk of them are low-grade earth tracks with few bridges or other drainage structures. A number of district capitals are not connected by road.

The tertiary road system consists in the main of earth tracks which are frequently impassable during the wet season.

The Ministry of Public Works is concentrating on completing the primary road system and the more important secondary roads. It uses relatively equipment-intensive methods with the bulk of the labour being provided by the "Labour Corps", a unit of the Afghan army.

The Rural Development Department (RDD) uses entirely labour-based methods. The policy of the department obliges it to use voluntary unskilled labour sometimes supported by food assistance from the World Food Programme (WFP).

2. The Rural Development Department (RDD)

More than 85 per cent of the population of Afghanistan lives in the rural areas and the basic economy of the country depends on their productivity.

The Rural Development Department provides direct assistance to village people to carry out schemes for which they themselves felt the need and to which they were prepared to give their labour and other resources. The basic policy of the RDD is therefore to help villagers to help themselves. This does not mean that it adopts a passive role. On the contrary, it adopts an active leadership role in stimulating ideas in the villages, discussing and identifying their needs and helping them to plan for themselves. The planning process, socio-economic survey and technical survey is carried out in close consultation with the villagers themselves. For example, the location of a road or the siting of a bridge is discussed with the village and if there are technical reasons for a particular location these technical reasons are explained to the villagers and their general agreement is obtained. No decision is imposed on a village and if agreement cannot be reached the project is not usually undertaken. The RDD provides assistance to a village on the understanding that the village itself will contribute its own resources to the project in terms of voluntary labour, local materials and sometimes a cash contribution. In this way the

execution of the project is very much a joint effort and when it is completed the villagers consider it as their project.

2.1 *Organisation structure*

The RDD is headed by a President with two Vice-Presidents, one in charge of the technical side of the department and the other in charge of administration. Under the technical Vice-President are four general directorates. These are:

a) Director-General, Planning and Programming: in charge of over-all planning, programming, budgeting and monitoring of all departmental activities both technical and non-technical.
b) Director-General, Technical Planning: in charge of all technical planning from the project initiation stage to the production of final drawings and estimates.
c) Director-General, Social Services and Agriculture: in charge of non-engineering programmes in agriculture, non-formal education, health, co-operatives, rural industries, etc.
d) Director-General, Construction: in charge of construction of roads, buildings, irrigation structures and canals, domestic water supplies, individual bridges, foot bridges, culverts, etc.

The RDD headquarters sends teams into the field to carry out socio-economic surveys, technical surveys and construction.

The initiation of projects takes the form of a request from the village to the provincial office of the RDD. The procedure is as follows:

a) a request is made from the village to the RDD provincial office;
b) the village is visited by a technician from the RDD provincial office who identifies the necessary local contribution of labour and materials;
c) the request is forwarded to RDD headquarters by the RDD provincial office with the information gathered in (b) and the recommendations of the RDD provincial Director and the Governor;
d) a socio-economic survey team from RDD headquarters visits the village and appraises the project;

e) if the project is considered viable a technical survey team from RDD headquarters surveys the site;
f) the project is designed in RDD headquarters and, subject to final technical and financial appraisal, is approved;
g) a mobile construction team from RDD headquarters is assigned to provide construction supervision and management, transport, eqipment, non-local materials and certain categories of skilled labour not available locally.

The construction team would be supplemented by voluntary unskilled labour provided by the village or villages and paid skilled labour either from the village or the nearby locality. The construction team lives on the site either in accommodation provided by the village or in tents. The construction team has administrative support from, and is supplied through, the provincial RDD office which is also responsible for seeing that the construction team gets the labour which has been promised by the village. If necessary the RDD Provincial Director will call on the assistance of the Provincial Governor to ensure this.

The construction equipment and transport available to these teams is extremely limited. This equipment is maintained by a small central workshop in Kabul which has inadequate resources to provide any field services except to nearby provinces. The RDD is procuring a considerable quantity of basic construction equipment. This is being financed from both Afghan, bilateral and multilateral sources, the total expected to be procured in the next two or three years amounting to about $3 million. This equipment is of two basic types:

a) To equip road and irrigation construction teams to enable better quality to be achieved and more economic design criteria adopted. These teams will operate on a labour-based basis, equipment and transport being provided only for those operations which are difficult or impossible by hand methods, e.g. rock drills, dump trucks, concrete vibrators and mixers, pumps, back hoes for deep excavation, etc.

   Three road teams and two irrigation teams are planned to operate in the more backward and thinly populated

provinces whose development requires particular attention.

b) Basic equipment for general use throughout the 27 provinces of Afghanistan. This equipment consists in the main of concrete mixers and vibrators and pumps.

A central workshop and mobile field teams are being set up to service this equipment.

The RDD has 27 field offices at provincial level. These offices provide liaison services between the provincial government, the villages and RDD headquarters. They generate new projects and are in constant direct touch with the villagers analysing their needs and suggesting solutions to their problems. These provincial offices also organise all local resource inputs to construction programmes and other RDD activities. They are responsible for the administrative and supply back-up to the construction teams.

In the longer term it is intended to decentralise the technical operation of the department to the provincial offices. At the present time however there is insufficient technical staff to be able to do this, the department having only 34 engineers to cover administration, management and technical functions.

Construction supervisors are recruited to RDD as 12th grade school leavers. They undergo a four months' course in construction methods at the RDD training institute at Gulzar near Kabul. This course is very basic and practical in nature. A construction handbook in Farsi has been prepared and forms the basis of the course. The course includes instruction on reading simple drawings, setting out, simple measurements of areas and volumes, the techniques of mixing and placing concrete, building in random rubble masonry and brickwork, the construction of simple formwork and falsework, etc. It also includes basic instruction in keeping simple site records and organising labour. On completion of their course they are assigned to a construction team to gain practical field experience. Refresher courses are held from time to time.

3. Construction resources

In any labour-based programme the major resource utilised is labour and, when voluntary or semi-voluntary labour is used, the well spring of this resource is motivation. The identification of this motivation and the means of sustaining it therefore

becomes a major consideration in the planning process. Three types of unskilled labour, entirely confined to males, are in regular employment on RDD schemes:

a) voluntary labour;
b) voluntary labour supplemented by food rations;
c) labour supplemented by food rations plus a small cash payment. (The value of the food ration plus the cash is always less than the ruling rate for paid labour.)

The motivation of the purely voluntary labour is the desire for access to the national transport system. The villagers of Afghanistan are acutely aware of the economic benefits arising from cheaper transport. In most cases the farmers are owner occupiers who have a farm surplus to export from their area. They are fully aware of the price differentials between the farm gate, the district market, the provincial market and the national market and the effect of transport costs and middlemen's margins on these price differentials. The motivation is therefore mainly economic although there is a growing awareness of the social benefits which can accrue. For example it is most difficult for a village to attract and keep a good school teacher if it is not connected by a road.

In the case of roads which serve a number of villages the incentive to provide purely voluntary labour varies with the location of the actual worksite relative to the location of the village. For example, in the case of a bridge those villagers living on the near side of the river have little or no incentive to construct the bridge as the benefits will go to villages located on the far side of the river. Where a village is located close to and on the near side of the bridge the villagers are a very convenient potential source of labour; however, if no benefits accrue to them they will not provide voluntary labour. The villagers living on the far side of the river who stand to benefit from the bridge may live a considerable distance away and it may not be feasible for them to travel to the worksite each day. In such cases it has been found necessary to provide an additional incentive to the villagers on the near side of the river to provide labour for the construction. This incentive usually takes the form of food rations provided by WFP. In some cases, where this incentive does not produce the necessary labour, a cash incentive is paid in addition to the food. This

cash incentive usually amounts to 20 per cent of the going wage rate.

Similar considerations apply to the construction of individual lengths of road which form parts of a complete road. Thus, on a particular length, all three types of labour, voluntary, WFP supported and WFP plus cash supported, may be working in the same gang at the same time; the proportion of each type depending on the benefits which that particular length of road will provide to each individual group.

Indigenous materials such as random rubble masonry, stone, gravel and sand aggregates for concrete, timber poles for concrete falsework are normally provided by the villagers themselves either in the form of voluntary labour for winning stone and aggregates or as a contribution from the village of a portion of their timber resources. As in the case of the voluntary labour similar incentive considerations apply.

Imported materials such as reinforcing steel and nationally indigenous materials such as cement and sawn timber are provided by the RDD. When planning the road the designs adopted deliberately minimise the requirement for materials which are not available locally. Thus for retaining walls dry random rubble would be used in preference to random rubble in cement mortar even when the value of the labour and materials in the former would exceed the latter. The greater the proportion of the resource inputs provided by the village itself the greater the sense that the road is *their* road.

The construction methods are entirely labour based. The only equipment which might be provided consists of:

a) pumps for dewatering structural foundations;
b) dump trucks where materials have to be moved beyond the range of hand carry or donkey transport;
c) concrete mixers — only in the case of large reinforced concrete structures (only two mixers are available for more than 90 projects):
d) concrete poker-type vibrators (the RDD's total holding is 3 units).

It might be considered that the use of voluntary labour as a construction resource would divert labour from agricultural production activities. In fact there is a considerable reservoir of unemployed and underemployed labour available in the villages on a seasonal basis.

4. **Design criteria**

The design criteria must always be considered as being flexible. They must also be compatible with the resources available and the construction techniques to be used. The design criteria discussed below are orientated to a situation of voluntary or semi-voluntary labour-based construction using the minimum of manufactured materials.

The use of unskilled village labour which works only on one project does not allow the building up of elementary construction skills in the labour force. The construction techniques involved must therefore be confined to very basic unskilled operations plus the use of any indigenous skill available in the local environment such as dry-stone masonry, construction of earth and stone coffer dams, etc. Designs have been deliberately developed which can tolerate such limitations in the resources available. This has led to the extensive use of random rubble masonry (both dry and in cement mortar), crib construction and gabion construction.

There is a further constraint to be considered when designing roads which are constructed by voluntary labour. The villagers will only do such work as they consider necessary to achieve the objective, i.e. a means of access to their village. Thus, if they consider that a 3.5 m or 4 m wide formation width is adequate it is most difficult to get them to construct the 6 m wide formation which might be dictated by considerations of traffic use and safety. Similarly if they do not consider a culvert to be necessary they will not construct it. In this type of work therefore design criteria must always be considered as guideline targets rather than an immutable minimum.

The design criteria adopted for tertiary roads in Afghanistan are based on the following assumptions:

a) that the Average Daily Traffic (ADT) does not exceed 100 vehicles per day (vpd);
b) that the traffic mix will be in the proportions of 17 per cent cars and jeeps, 33 per cent light trucks and buses (1½ tonne payload or 20 seats) and 50 per cent medium trucks and buses (6 tonne payload or 40 seats);
c) that traffic delays up to 24 hours are acceptable.

The rural tertiary road design standards in use are given in Annex 1 at the end of this chapter.

Various types of structure are now in use. Most of these

make maximum use of local materials. In the case of bridges, for instance, timber trusses up to 30 metre spans have been designed. In the case of culverts, the usual type used up to the present time has random rubble masonry walls with reinforced concrete slab decks. Pipe culverts are seldom used because of the constraints of casting the pipes on the sites with the lack of control over concrete quality. Transport problems preclude the use of pipes manufactured at central locations.

Retaining walls and bank protection are generally of random rubble dry-stone masonry. The village people have developed skills in its use as it is used for boundary walling, housing and land terrace wallings. Such walling is often "stitched" with brushwood or timber poles.

Caseways or "saddle" bridges have often been adopted because in Afghanistan's semi-arid climate there are a large number of stream and river crossings which are dry (or have very small flows) for the greater part of the year. Such drainage channels are called washes. At certain times, often for very short periods, such washes run with considerable flows. They are often very wide (up to 1 km) and to bridge them with a dry crossing for tertiary road traffic volumes would be uneconomic. In some cases the flow pattern is such that for nine months of the year the flow will be nil or minimal followed by three months of significant flow interspersed with periods of high flow of very short duration. The solution adopted for this situation is to construct a causeway which has a cross section designed to discharge the three months significant flow at a fordable depth (usually taken as 35 cms) allowing the road to be interrupted during the short periods of high flow. Such causeways may be of unvented masonry or pervious gabion construction. In cases where there is a significant dry-weather flow, slab culvert vents are provided.

The roads constructed by RDD are not normally paved, consisting of earth or improved earth surfaces. In the rare cases where gravel surfacing is provided it is usually spread in a number of thin layers, each layer being compacted by traffic. No compaction equipment is owned or used by RDD. Compaction of embankments and behind abutments of bridges and culverts is achieved by the use of wooden-pole rammers. Action is being taken to acquire a limited number of vibrating rollers and impact rammers to improve compaction in such cases.

5. **Stage design for roads**

The concept of stage construction of roads is well-known. It consists of the construction of the various elements of a road, earthwork, sub-base, base and surfacing in stages. Each stage is constructed at the point in time when traffic volumes dictate that particular stage. Thus, in the first instance, when low-traffic volumes are forecast, the road is constructed with narrower formation widths and lower pavement strengths than are predicted for the final stage.

In such cases it has usually been assumed that the road must be constructed on the same horizontal alignment in the first stage as will be required in the final stage. The vertical centre line may be adjusted in stages to accommodate the progressively higher sight distance standards demanded by increasing traffic volume. The same may apply to the widening of cuts or removal of obstacles to increase horizontal sight distances. The horizontal alignment of the centre line, apart from minor adjustments such as the insertion of transition curves and adjustments to curve radii within the earthwork width, is however usually fixed by considerations of the final traffic volume to be accommodated.

This general method of stage construction is a valid and economic concept in flat or rolling country as the effect of higher horizontal alignment standards involves a comparatively small increment in earthwork costs. For example, the cost differential of joining tangents by large radius curves instead of small radius curves is usually a small percentage of the total earthwork cost. In mountainous country however, where a road is running up a steep-sided valley (a very prevalent case) the cost differentials may be very high. If a large number of small radius curves are acceptable the road centre line can follow the contour with a minimum of earthwork. A higher standard of curvature and sight distance will involve cutting through spurs and filling through re-entrants. This not only involves higher volumes of earthwork but also the longitudinal movement of earth from cut to fill as opposed to the lower, standard case of lateral movement of earth short distances from cut to downhill waste. In addition, the filling of re-entrants on steep-side slopes often means considerable expenditure on retaining walls and pre-fill benching.

In such cases the principle of stage design can often achieve significant savings on initial construction costs. There is no doubt that such an approach will result in a higher total construction investment by the time the final stage is reached. However, if the traffic growth rate is expected to be small and the initial traffic volume is low (less than 50 vpd) the effect of postponing the capital expenditure required by the later stages can, by the effect of discounting the costs, result in lower net present costs. This effect, in cases where benefits are low, can have a decisive effect on the economic equation and convert a non-viable to a viable investment.

The question of ruling and maximum gradients, which are often critical design parameters in mountainous regions, requires special attention if stage design is to be adopted. The gradient criteria should be applied to the *final improved alignment* and the profile of the initial alignment adjusted to control points where the initial alignment crosses the final alignment. Thus the distance along the centre lines between two coincidental points on the two alignments might be 1,000 metres on the initial alignment and 500 metres on the final alignment. If the final design grade were to be 5 per cent, i.e. a rise of 25 metres over the 500 metres section then the gradient on the initial design section would have to be restricted to 2.5 per cent so that when the final design is achieved the final design gradient criteria can be met.

A second point requiring careful planning is the question of culverts and drainage structures. In the initial stage permanent culverts should only be located in positions where the initial and final alignments coincide or nearly coincide. In other cases either road dips (pitched to prevent erosion) can be provided, or dry-stone random rubble abutment walls supporting precast concrete slabs should be used. At the final stage these can be transferred to the final location culverts.

Bridges should be considered as control or obligatory points and constructed on the final alignment. In cases where this proves very difficult to achieve, prefabricated bridges such as Bailey can be used. Alternatively where traffic growth indicates that the final alignment will not be required within the life span of a temporary bridge (say 15-20 years) then a timber structure can be provided. In cases where initial traffic

volumes are low (say less than 25 vpd) interruption of traffic for limited periods (say 24-48 hours) can usually be accepted and pitched fords can be constructed on the initial alignment.

The decision to adopt stage design must be preceded by a carefully considered judgement of the traffic growth pattern (an analysis based on statistical method is seldom possible). An element of risk is of course always involved but the possible savings offered by the method are such that they allow much needed access to be provided to villages and small towns which would otherwise remain in isolation with all that involves in terms of the lack of economic and social development.

This approach can also offer a solution to the dilemma of being unable to construct a road to the final alignment requirements because its construction would require mechanical equipment (heavy rock cuts, etc.) which is not available in the country. The stage design approach enables a road to be built, as the side hill cut operation can always be achieved by hand labour using handtools. Thus, road access can be provided in many cases where the conventional design approach would involve costs which rule out viability. In such cases the villages and towns involved are condemned to indefinite stagnation in an isolated environment.

6. Organisation and management of labour

There are four distinct elements in the process of converting human physical energy into infrastructure. These are:

a) the generation and maintenance of the energy output itself;
b) the acquisition and application of skill;
c) the identification and provision of optimum tools and equipment to provide the means of converting the energy and the skill into physical infrastructure;
d) the organisation and methods used in the construction process to co-ordinate the three elements (a), (b) and (c).

In the normal case the maintenance of output is a function of incentives. The incentive may be financial reward or it may be by the negative incentive of a closely supervised environment which insists on a certain minimum output as a requirement of employment. Financial incentives may be on an

individual or on a group/gang basis. Such incentives include piecework where payment is in direct proportion to production and task plus bonus systems where a minimum task is linked to a day's work and additional payment is made for each unit of production achieved in addition to the minimum task. In some cases a mixture of the financial incentive and supervision incentive systems operates when labour contractors are employed[1], the contractor being paid on a production basis and his labour being paid on a supervised fixed-wage basis. But such systems are not considered desirable as they lead to the exploitation of labour by labour contractors.

In the case of purely voluntary labour the incentive, while it has an individual element, is essentially a group incentive and not directly linked to financial reward. As the labour is voluntary the relationship between the supervisor and the labour is quite different than that between a normal employer and employee. In the case of voluntary labour it is absolutely essential that the supervisory personnel adopt an attitude of offering their services to the village to assist them in achieving their objective. In the case of structures the fact that RDD provides cement and reinforcement provides some hold over the village but in the case of roads the provision of such materials is often minimal and control over the construction must be achieved by the co-operative attitude and leadership qualities of the RDD personnel.

The case where voluntary labour is supported by WFP aid lies between the purely voluntary case and the normal case. However the Afghan farmer is a fiercely independent individualist and the methods of man management adopted must tend towards the voluntary-labour case rather than the employed-labour case.

There are certain construction or quasi-construction skills which are inherent in Afghan village life. These vary somewhat in differing areas of the country in sympathy with the locally available construction materials. One skill which is very widespread is the management of flowing water. Irrigation is the life-blood of the Afghan farmer and he is highly skilled in drainage works, the construction of coffer and diversion dams. In areas where stone is available, masonry skills both in dry-stone walling and mud-mortar walling are indigenous. Labour which works on construction projects on a continuous

basis although nominally unskilled, has in fact significant skills both in excavation work and in support of skilled artisans. Such labour also has an awareness of the construction site environment with its attendant hazards. The acquisition of these skills is usually by a process of absorption through working with experienced construction labour. In the case of construction labour which is voluntarily supplied by a village for an isolated project the construction operation is a new experience and there is no core of experienced labour to emulate. This labour has to be trained in organisation methods and safety precautions completely from scratch by the RDD supervisory personnel. This process has to be repeated for every job because in every new project the labour, being indigenous to the village concerned, starts with no construction experience.

Before the construction team arrives on the site a construction plan has been prepared at RDD headquarters which shows in bar-chart form the starting date and time programmed for each operation and also the resource inputs required. Earthwork on roads is often carried on at several locations at the same time. These locations are selected on the basis of convenient distances from individual villages. Having identified the sections of road and the quantity of labour to be provided by the village or villages assigned to that section, the technician meets the Malik (headman) of the village and discusses the construction of the section in detail. The work is set out and the shape of the excavation is shown to the villagers. Work then proceeds supervised by the construction supervisors who indicate lines and levels and advise on management at the site to achieve the optimum productivity. This advice covers such points as the best division of labour between excavators, carriers, placers in fill or throwers to spoil. As has been stated previously the productivity of purely voluntary labour is a direct function of their own motivation and site management is largely confined to showing the labour how they can achieve greater productivity with the same effort.

In the case of labour supported by WFP food rations, reward (in terms of food rations) can be correlated with productivity. Production norms have been established for excavation tasks. These norms have been based on six soil categories linked to the process of excavation (table 1).

Table 1: Man-hours of labour-required per cubic metre

	Soil type[1]					
	1	2	3	4	5	6
Excavate into barrows or baskets	1.0	1.6	2.0	3.0	6.0	10.0
Excavate into trucks	1.6	2.2	2.8	3.6	6.6	10.8
Trench excavation 1.5 metres	2.0	3.6	4.0	5.0	10.0	14.0
Hauling in barrows over 20 metres	1.0	1.1	1.2	1.3	1.4	1.4
Hauling by baskets over 20 metres	1.8	1.9	1.9	2.1	2.5	2.5
Spreading and compacting in 15-cm layers	1.0	1.0	n.a.	1.0	n.a.	n.a.

[1] Soil type
1 – Loose sand or soil
2 – firm sand or soil
3 – clay or heavy adhesive soil
4 – compact soil or gravel
5 – soft rock
6 – hard rock

These norms are translated into metre-runs of completed road for the various configurations in the section being constructed. These configurations normally fall into four general categories:

A. Flat ground, no embankments. Side drains excavated and filled to centre to form camber. 5.50 m wide between drains.
B. Embankment 1 m high, 6 m wide.
C. Side hill cut on side slopes up to 30°.
D. Side hill cut on side slopes over 30°.

The quantity of excavation, carry, and filling in each metre-run is calculated for the average section and the number of man-hours work involved. This is translated into rations of food on the basis of eight hours work. The number of rations allowed per metre-run for each length of each configuration in

the section is then agreed with the labour force. The section is then divided into "lengths" with an approximately equal number of rations payable for each length. Each length is marked and allocated to a group of labour (a gang). Payment of rations is made on production achieved. In cases where the food ration is supplemented by a cash payment the cash payment is made on an individual man-day basis rather than on a productivity basis. This is done to comply with government accounting regulations.

Skilled labour employed on the construction of bridges, culverts, retaining walls and drainage outfalls is paid on a man-day basis. WFP-supported unskilled labour is paid food rations at the rate of one ration per man-day worked.

7. **Methods, tools and equipment**

The greatest bulk of the work performed is in excavation which is carried out entirely by hand (including rock drilling). The tools used are:

a) long-handled, round-mouthed shovels;
b) picks with sharp and chisel points;
c) crowbars with moil points for soft rock and boulder excavation and with chisel points for rock drilling;
d) two-man carrying litters.

These tools are the traditional tools of the farming community of Afghanistan.

The bulk of excavation in road works is in side hill cut or in the excavation of parallel drains on level ground using the material excavated from the drains to form a central camber. Movement of material from the excavation to spoil rarely exceeds 10 m and is usually of the order of 5 to 6 m. In the case of side hill cut excavated material is moved laterally to waste down the hillside. This is achieved by double handling the material, the excavator throwing to the excavated bench and a second man throwing it to waste by shovel. The number of excavators served by one double handler depends on the soil category involved and the length of throw. In the case of soil category 4 (see section 6, seventh paragraph) which forms a large proportion of the excavated material, one double handler can serve two or three excavators. If the distance to be moved is more than 6 m (two throws, triple handled) carrying litters may be employed. Attempts have been made to introduce

wheelbarrows as these have about half the labour input of a two-man litter. These efforts have had mixed success but where sufficient barrows can be obtained of suitable quality the indications are that they will be accepted in most cases. The use of baskets, headpans, etc., is not accepted by the Afghan farmer who is not accustomed to carrying any load on the head. Where carries exceed about 30 m, donkeys with twin panniers are used if they are available and can be spared from other transport demands. In cases where there are other competitive transport demands at the time of construction (e.g. taking the surplus crops to the bazaar), donkey transport has to be hired, at other times it is provided free by the village. In cases where long carries (in excess of 1 km) are involved the RDD provides dump trucks. These cases are usually confined to hauling construction materials such as masonry stone and concrete aggregates rather than excavated material to fill or spoil.

Rock drilling is done with crowbars which are "jumped" in the hole (not driven by hammer). A group of three men are usually employed. Two men "jump" the bar and the third washes and clears drillings from the hole, a length of hooked wire being used for this purpose. The bars are usually 1½ m long and 40-50 mm in diameter. Productivity achieved depends on the rock type but rarely exceeds 1 m per shift. It is therefore a slow and laborious process which often holds up other work. The RDD is procuring self-contained mechanical drills to speed up the process. Due to access difficulties the use of air-compressors and jack-hammers will be confined to sites where truck access is possible.

The greatest problems are encountered when excavating in pits or trenches for foundations, particularly to bridge piers and abutments where dewatering is necessary. The normal method is to construct a coffer dam or diversion dam of mud and stones reinforced with brushwood. The excavation is carried out in open pits without timbering which means that, allowing for tolerable side slopes, the area of the excavation is large. In gravel and boulder beds where percolation rates are high the volume of water entering the excavation is very high and when heads of more than about 2 m are involvd the inflow becomes unmanageable. 10 cm and 15 cm suction centrifugal pumps are used but in practice it has been found that foundation

depths beyond about 2 m are extremely difficult to achieve in the dry. This is being tackled in a number of ways:

a) by modifying designs by adopting shallow self-scour protecting structures (gabion and cribs);
b) by modifying designs by adopting open caissons to reduce foundation areas and reduce inflows;
c) to acquire excavation equipment (back hoes);
d to introduce timbering techniques.

It is difficult to introduce new tools and techniques to the extremely conservative Afghan farmer. This is particularly the case where voluntary labour is involved. The farmer will do it his way or not at all. It requires great persistence and the clear demonstration that a method is easier if there is to be any chance of getting it adopted. Construction supervisors and field engineers and technicians continuously try to improve techniques but the process is slow. A second problem when the labour force continuously changes from village to village is that by the time one village is convinced that a new technique is worth while a new batch of villagers from another village takes over the construction process.

8. Special considerations involved in the use of voluntary village labour

The primary objective of the Rural Development Department is to raise the standard of living of the rural people of Afghanistan by providing such supplementary inputs to the efforts of the people themselves as will help them to greater efficiency, productivity and social well-being. In the context of road building, it is not RDD's primary objective to construct the roads themselves but to use the road-building process as a vehicle for enhancing the self-reliance of the villages concerned and to increase their capacity to manage their own resources for the benefit of the community.

This policy of giving primary importance to voluntary village participation poses a number of problems which are not generally encountered when planning comes from the top downwards and construction is by paid labour.

The tertiary road construction programme emerges from the aggregation of village requests to construct roads and their agreement to provide the labour to do so. The shape of the programme and the relative economic priorities of the projects

comprising the programme are not therefore based on rational over-all regional requirements. When the RDD receives a request from a village to build a road a socio-economic survey is carried out which examines the transport need and makes a rough comparison between benefits (both quantifiable and non-quantifiable) and costs. The voluntary labour and local materials contribution is not counted in these costs as they are not transferable to other alternative projects. If this survey demonstrates viability the project is normally approved. When considering viability in this context the position of the road vis-a-vis the rest of the road system of the region is considered and a project would be approved provided it contributed to the totality of the transport system. However it might not, as an individual road, make a higher contribution than any other alternative. In this sense therefore it would offend against the principles of rational planning that investments should be progressively made in those projects giving the highest return. The attitude adopted by the RDD is therefore dictated by their basic policy of bottom-up initiative and not by the strict rationale of economic planning criteria.

Typical costs of tertiary roads in Afghanistan range from $1,500 per km for roads with few structures and no major bridges, to $12,000 per km for roads in isolated mountainous areas involving paid labour and considerable structural work in retaining walls, culverts and bridges. These costs demonstrate the simple design criteria adopted.

Design criteria which are based on good technical practice and considerations of functional efficiency and safety are not always self-evident requirements to a village which is required to make major contributions to a scheme. For example, a road is now under construction to link the Parsa valley to the main road in the province of Parwan bordering Central Afghanistan. This road is entirely in side hill cut through difficult boulder-strewn soil, rock talus slopes and, in some lengths, solid rock. Excavation conditions are difficult and laborious. The design criteria call for a cut bench width of 6 m, 5.50 m for the formation and 0.50 m for the hillside drain. The villagers have excavated a bench 3.5-4.0 m in width and light buses are negotiating the road and providing a transport service. The villagers are most reluctant to provide any further labour to widen this bench to the design width and it may prove impossible to

achieve the design criteria. The village has achieved its objective, a transport connection which is operating. As far as they are concerned this is enough. On this same road there is a difficult climbing section involving a double hair-pin bend. Drystone walling has been built to provide the bare minimum geometry which will enable a light truck to negotiate the bend by reversing on the hair-pin bends. This is a dangerous procedure and from a highway engineering point of view the design is unacceptable. A new design has been prepared which will require new retaining walls to be constructed. The first reactions of the villagers to providing labour to construct these walls was unfavourable but it is hoped that they will be persuaded to construct the new design before a major accident occurs.

Labour management has to be based on persuasion and mutual respect between the RDD team and the village. It cannot be based on the usual criteria of labour discipline and financial incentive. The incentives and motivation behind the village's voluntary contribution are discussed in section 3 (paragraphs 1-4). This requires an entirely different style of management based on leadership and sympathy rather than "commercial" methods. Arising from this is the fact that the construction processes involved have to be discussed in much greater detail to convince the villagers that the method advocated is to their advantage.

The present policy of initiation, planning and execution of tertiary road projects from the bottom up and with the close involvement of the village at all stages will be continued. As virtually the whole of village contributions consist of unskilled labour the use of this resource is obligatory which in turn means that labour-based methods must continue to be used. This policy is not confined to road construction but extends to all infrastructure works carried out by the Rural Development Department.

Notes and references

[1] Editor's note: the use of labour contractors is not encouraged by the ILO as it often leads to abuse. Their use is covered by the Convention concerning the protection of wages, Convention No. 95, adopted by the International Labour Conference in September 1952.

Annex I — Tertiary road design standards

a) formation width:
   i) in cut 5.50 m excluding drains;
   ii) in fill 6.00 m;
   iii) in rock 3.50 m excluding drains;

b) carriageway width 3.50 m;

c) passing places:
   i) generally 6.50 m wide, 35 m long at intervals of 500 m or the sight distance whichever is the less;
   ii) in rock cuts 5.50 m wide 25 m long at intervals of 150 m;

d) gradients:
   i) over-all gradients: earth surfaced 3 per cent, gravel surfaced 4 per cent;
   ii) maximum gradients: earth surfaced 10 per cent, gravel surfaced 12 per cent.

   Gradients through sharp bends, particularly hairpin bends, should not exceed 5 per cent between the tangent points of the bend plus 15 m at each end;

e) curvature: the maximum radii compatible with the terrain should be adopted with the following minima:
   i) minimum inside radius of carriageway — 9 m;
   ii) minimum outside radius of carriageway — 13.5 m;

f) surfacing:
   i) generally gravel surfacing will only be provided when traffic exceeds 100 pcu per day (cars 1 pcu, light trucks 1 1/2 pcu, medium trucks 3 pcu);
   ii) gravel surfacing will also be provided in particular cases where soil moisture or drainage conditions make it necessary;
   iii) in cases where the natural earth is of a plastic nature, cohesionless material such as sand or fine gravel is mixed with the top of the formation to stabilise the surface;
   iv) in other cases the natural formation will be used.

CHAPTER 8. THE BORDER ROADS ORGANISATION IN INDIA: LABOUR-INTENSIVE CONSTRUCTION ON A LARGE SCALE

by Major General J. S. Soin
Director, Border Roads Organisation

1. Introduction

The Border Roads Organisation (BRO) was created in 1960 to undertake road construction programmes in North and North-East India in areas where little or no road existed. The urgency for socio-economic development of these backward areas and the impediments to achieving this owing to the lack of road communications resulted in a crash programme of priority roads being roughly assesed in 1960 and efforts made to mobilise resources. The programme of road construction envisaged in the formative stages of the organisation was the completion of about 3,000 kms of roads (new construction and improvement) over a three-year period.

It was expected that when the objectives of the crash programme were realised, it would be possible for other development agencies to carry out maintenance and improvements and to expand the road communication complexes with many more arterial routes and feeder roads in the years ahead. However, the need for faster and dependable road communications systems increased and the BRO was entrusted with the construction of more roads on the basis of their performance and expertise.

2. Terrain and climate — effect on technology, design and specification

The BRO had to undertake work in areas of difficult terrain and extreme climatic conditions. The terrain is mostly mountainous, with many escarpments where the strata is geologically

very young, and unstable. The roads have been constructed from the foothills going up to 5,000 metres altitude.

There are regions which are generally arid and experience heavy snowfalls during winter months, and where very low temperatures obtain, in certain places as low as -40°C with high velocity winds as well. In other regions, forest growth is dense and rainfall is as high as 500 cms per year with frequent high-intensity rainfall during short periods, often associated with cloudbursts. Severe weather conditions pertain for almost five to six months of the year.

These climatic conditions obviously have an adverse effect on the efficiency of workmen and on the performance of machines and materials. Terrain and climatic conditions have, therefore, a special significance and have long-term effects on the organisational set-up, the design and specifications for the roads, the type of technology and the mode of working.

Initially, the bad terrain and extreme climatic conditions were governing factors in the adoption of machine-intensive work on roads. Availability of labour was also found to be poor as the working conditions were not conducive to attract people to venture into such areas. However, with the opening up of the areas and development taking place these areas became more habitable and working conditions improved so that it was possible to make a beneficial transition towards more labour-intensive methods.

3. **Design standards**

The width of roads constructed was that considered adequate to allow free one-way traffic or restricted two-way traffic. While adopting these specifications, it has also been kept in view that it will be possible to upgrade the roads if such a necessity arises due to traffic growth. A ruling gradient of 1 in 20 for hill roads was fixed keeping in view the effect of altitude and snowfall on vehicles.

To make the best use of local materials and those produced during the course of earthwork such as trees, stones and so on, it was decided at the start to provide temporary log culverts, retaining and drainage structures with stone masonry (wherever possible with dry stone), to use stone as soling to form the sub-base of the pavements, to limit paved roads to 3.75 metres and adopt a simple type of wearing

course, like surface dressing, for the pavement. Even in the construction of bridges for spanning small streams and major rivers, prefabricated equipment components were accepted, to be replaced with permanent bridges later on.

4. Selection of technology

The road construction programmes entrusted to the BRO were very large and were required in a relatively short period.

It became clear that the appropriate technology for road construction would be a combination of equipment-intensive and labour-based methods. This principle has been quite successfully adopted by the BRO not only in respect of road construction but for maintenance as well.

4.1 *Balancing of machines and labour: new construction*

For reasons outlined previously, it was initially planned to make the BRO basically machine based. However there was a considerable gap between the availability and requirements of machines necessary to realise the stated targets. In order to make up these shortfalls by manual efforts, it was necessary to evaluated the relative effects of using manpower as against machines and to examine the extent to which the labour-based methods could be used in realising the targets without in any way increasing the fixed and predetermined overhead costs. Accordingly, the BRO carried out a study of the labour required to replace machines for the major items of works in road building, namely earthwork in road formation, protective works and pavement construction. The results of the study are summarised below:

a) *Number of men required to replace equipment*
   - i) Crawler tractor (150-180 hp) : 200 men
   - ii) Compressor : 170 men
   - iii) Stone crusher (5-6 tons/hour) : 100 men

b) *The number of men required for 100 kms of road length per year even if earthwork and surfacing is done by equipment*
   - i) Earthwork : 3,000 men per day (jungle clearance, dressing of hill slopes, assisting machines, levelling road formation and so on)

ii) Protective and drainage works : 1,300 men (all works) per day

iii) Pavement : 1,900 men (stone collection, feeding of crushers, spreading of various courses, watering, assisting road rollers, berm dressing and so on)

Total : 6,200 men per day

c) The required labour force to execute 100 kms of road construction by various percentages of machines and labour (assuming that protective works have to be done only by labour) is depicted in Figure 1 overleaf.

FIG. 1 MACHINERY AGAINST LABOUR

d) It will be seen from Figure 1 that the labour requirement steadily increases with the reduction in the proportion of machines. According to the graph the annual requirement of labour for executing 400 kms of road works per year is of the order of 25,000 men if equipment-intensive methods are used.

The use of a large labour force for road works poses recruitment problems which imply increases in the number of supervisory and administrative staff. Resorting to man-intensive earthwork has its own drawbacks and the deployment of men over virgin stretches of land becomes difficult. Further, wide variations in the requirements for labour will create problems at both the recruitment and discharge stages. The most important factor that has a bearing on costs is the requirement to accelerate road formation works. If this is not done the provision of the surfacing and protective works is delayed and causes an escalation of direct and indirect costs.

Nevertheless the move to a more labour-based method of working was such that during the peak years of work, i.e. 1965-68, around 25,000 regular departmental labour supplemented by about 65,000 casual labour were employed.

5. **Organisation**

The work of the BRO was a pioneering effort to open up inaccessible areas. To manage the technical and administrative problems that are encountered while working in difficult terrain and climatic conditions, a self-contained organisation was considered essential. This would have its own complement of men, machinery and stores, and with the capability of carrying out planning execution, management and inspection.

It was decided therefore that the organisation should be set up on a "task force" pattern charged with the specific responsibility of road development. The organisation devised for the task force was such that it was capable of tackling all the jobs that arise during the course of construction as well as carrying out the administrative and logistics functions. The evolution of the organisation from 1960 and the modifications carried out over the years as the result of experience are described below.

The task force, headed by a superintending engineer, was charged with the responsibility of technical and financial control over the constructional activities. The task force was given three types of *unit* to enable it to discharge its functions:

a) construction units;
b) logistic units;
c) administrative units.

Construction units are allotted to task forces for the following purposes:

a) construction company in charge of a sector of road;
b) earth-moving plant company holding a complement of tractors for earthwork. This provides the plant needs of the construction company;
c) construction equipment company for holding equipment like compressors, rock drills, stone crushers, concrete mixers, and so on, to be used by the construction company;
d) pioneer company to provide department (regular) labour force.

To assist the construction companies in their tasks, the following supporting units were provided:

a) field workshop to provide repair and maintenance facilities for vehicles, plant and equipment;
b) transport company/transport platoons to supply vehicles for construction and administrative purposes.

To provide administrative services, the following units were constituted:

a) supply platoons to provide rations and primary and secondary oils;
b) workshop and park company to hold and supply stores;
c) medical units;
d) postal sections.

All the units indicated above were placed under the task force which controlled the ground organisation and whose functions were technical, financial and administrative. The task force normally had two or three construction companies and one each of the supporting and administrative units and two pioneer companies. Each of the task forces were capable of being employed at any time on about 100 kms of new roads in different stages of development.

A task force with the organisational structure described was found to be effective in the formative stages. However, in due course of time, with the progressive improvement of communications and the necessity to adopt superior specifications including provision of large-scale protective work and all-weather pavement, it was found necessary to reorganise some of the units on a functional basis.

Therefore, a review of the functioning of the units of the BRO was carried out.

The review resulted in the following types of unit under the task force:

a) road construction company;
b) road maintenance platoon;
c) surfacing platoon;
d) permanent works platoon;
e) formation cutting platoon;
f) transport platoon.

The expected output of the functional platoons is as follows:

a) formation cutting platoon: 20 kms of road per year;
b) permanent works platoon: 300,000 dollars per year;
c) surfacing platoon: 20 kms of pavement per year;
d) road maintenance platoon: 100 kms road maintenance; 25 kms of renewal of wearing course and 80,000 dollars of protective works.

Each task force may have two to four road construction companies. Each road construction company may have either two formation cutting platoons or three surfacing/permanent works platoons or five road maintenance platoons with a budget of 1 million dollars per year. As such, a task force has the potential to undertake works worth 3 million dollars per year.

Such an organisation has been found to function effectively. The controlling headquarters for this organisation is that of the chief engineers of projects who each have two to four task forces under them. The project chief engineer has over-all responsibility for the task forces under him and his jurisdiction is defined from work and geographical considerations. The chief engineer is responsible to ensure the arrangement of all resources as well as their management and personnel administration.

The projects come under the over-all control of the Director-General, Border Roads who is responsible for co-ordinating the functions of the organisation, laying down technical standards, procurement of vehicles, plant and equipment as well as the allocation of resources and funds to projects.

For the construction of 100 kms of new road in one year the rough requirement for the major categories of personnel and machinery is tabulated below:

	Category	Requirement
	Manpower	
1	Officers (engineers)	100
2	Supervisors	
	(a) senior	200
	(b) junior	250
3	Tradesmen: (masons, concretors and so on)	750
4	Operators and mechanics	1 000
5	Regular labour	3 000
6	Casual labour (skilled and unskilled)	9 000
	Machinery	
1	Light vehicles	100
2	Load carriers (3 to 7 tons)	350
3	Crawler tractors (150-180 hp)	45
4	Compressors (2 drills)	45
5	Road rollers	25
6	Stone crushers up to 10 t/hour	20
7	Bitumen heaters	15
8	Hot-mix plant (20-30 t/hour)	3
9	Concrete mixers (up to $0.3m^3$)	6

6. **Employment of labour**

6.1 *Departmental (regular) labour*

Both skilled and unskilled labour is employed on road works.

The BRO has a certain complement of these in its own establishment who are regular government employees paid according to fixed scales of pay. Certain special concessions like rations, clothing and so on are also provided. There are some 3,000 skilled and 20,000 unskilled workers in this category. They are moved from place to place as necessary. Their cost to the BRO is about twice that of casual labour.

6.2 *Casual labour*

In many instances the BRO has supplemented departmental (regular) labour with a large complement of civil labour recruited locally or from outside and introduced into the area. Civil labour is employed on monthly rates of pay but they are not regular government employees and do not have any permanent hold on their job. Their services are liable for termination at any time and are governed by normal labour laws.

Imported labour is recruited from outside the immediate project area when there is scarcity of local labour. They are

recruited for a minimum period of six months and are paid train/bus fares to the project site from the place of recruitment and some pocket expenses. The facilities provided to the casual labour both local and imported are as follow:

a) issue of ration on payment;
b) limited medical services;
c) weekly paid holidays;
d) improvised living accommodation;
e) death/injury compensation.

The wages fixed for civil labour are not less than those for similar categories employed in other government agencies in the area, and also take into account the difficult working conditions where they are deployed. The range of rates prevalent are:

a) unskilled: 20-25 dollars per month;
b) skilled: 25-30 dollars per month.

The availability of labour is seasonal as labour is mainly drawn from rural areas and they go in search of employment during the non-agriculture season. By and large, the BRO has been able to get an assured supply of labour because gangs or groups of labour have been working for years with particular units. Thus, they have moved with the units wherever new works are taken up: moreover labour has taken up permanent residence in many of the areas where road communications have been developed and are employed as maintenance gangs.

The average strength of skilled and unskilled casual labour employed by the BRO over the last few years is 3,000 skilled and 60,000 unskilled.

7. **Contracts**

The bulk of the work of the BRO is done departmentally. However, with the opening up of the areas, the availability of construction contractors, as well as contractors for transport, has increased considerably. In view of this, it was considered desirable to entrust some works on contract, at least in the areas where development has taken place. Accordingly, certain works like supply and transportation of stone, aggregates, sand and so on, and to a limited extent construction of small items of work like culverts and retaining walls, are being awarded to contractors to augment departmental resources

especially vehicles. In addition, the construction of major bridges is being entrusted to specialist firms.

8. **Logistics**

One of the major problems of the BRO when operating in remote and difficult areas is logistics. It involves not only procurement and provisioning of an assortment of vehicles, plant and equipment and other stores but also transportation to work sites situated as much as 500-600 kms away from rail-heads.

Enormous efforts are required to position all types of stores and vehicles, plant and equipment at work sites at proper times and in predetermined quantities. These should be available in a state of fitness for utilisation. Unless the logistics problems are tackled, the constrcution work will not proceed as programmed.

One of the responsibilities of the Director-General, Border Roads and Project Chief Engineer is to look into the aspects of logistics and inventory management. Base workshops cater for repairs of vehicles, plant and equipment and provide a spares back-up. Stock and inventory control functions for constructional stores are attended to by stores depots under the project chief engineers.

9. **Conclusions**

Developing countries embarking on road construction programmes have to choose between labour-based and capital-intensive methods keeping in view the problems obtaining in their countries. It is possible to undertake large-scale construction programmes by organising the construction force modelled on the lines of the BRO.

The BRO has moved steadily over the years from a reliance on equipment-intensive methods to the use of effective labour-based methods.

It should be borne in mind however that the BRO is run along military lines. Whilst this produces relative efficiency it is not necessarily representative of labour-based work throughout India. It does indicate however that even when large numbers of unskilled labour are employed it is possible to organise and manage labour-based methods effectively.

CHAPTER 9. SOCIAL AND ENVIRONMENTAL FACTORS: LESSONS FROM IRAN

by R.S. McCutcheon

1. Introduction[1]

Several innovatory rural development programmes have recently been initiated in Iran. One of these — the Selseleh Integrated Development Project (SIDP)[2] is based in the Alashtar Valley of the Lorestan Province, about 450 kms south of Tehran. The town of Alashtar has a population of 6,000 inhabitants and is the commercial and administrative centre of a fertile and well-watered plain, which has over 200 villages whose total population is about 40,000. The people of the plain are members of the Lur Tribe, partly settled and partly nomadic. The income of the region derives almost entirely from nomadic pastoralism and agriculture, the main cash crops being wheat, soy beans and sugarbeet.

The SIDP was based upon notions of self-reliance and participation. Particular stress was laid upon the need for both collective and individual development to be endogenous (i.e. to grow from within the local society itself) and not be based upon alien models. Trainees were to be selected from among the local population. At the end of their training programme it was intended that they should return to their villages and act as "agents of change". The trainees would help the people decide upon their own developmental priorities. Concurrent with the training programmes it was intended that the project should initiate the provision of a developmental infrastructure (public baths, schools, roads, etc.) in accordance with the principles of endogenous development.

The headquarters of the project is in Teheran which is mainly responsible for budgetary matters and liaison with other ministries. The total budget for March 1975 to March

FIG. 1 ALASHTAR (1: 250000)

1976 was of the order of 10 million tomans ($1.4 million)[3]. Field programmes were devised and administered in Alashtar itself.

The large budget of the project allowed the purchase of significant amounts of equipment. Before the start of the project the town of Alashtar boasted perhaps four jeeps and three trucks. After one year the project had imported a garage of over 20 landrovers, jeeps and vans, as well as four 13-ton trucks, ten tractors and trailers and various equipment, and the staff attendant to the equipment.

2. **Road construction and the SIDP**

Road-building was also carried out under the auspices of the project. At the time of the author's arrival the road-building work showed the results of the theoretical framework of the project combined with the loose decision-making process and ample funds. Firstly, it was claimed that, in accordance with the theory of endogenous development, low-cost minor roads should be built by voluntary labour and that experience in Alashtar proved that they could be built by these means. Secondly, it was claimed that voluntary labour could also form the basis for constructing an all-weather road across the mountain between Espege and Sarob Narh (see figure 1), thus forming a major route between Alashtar and the City of Borujerd. Thirdly, work had actually started upon this route across the mountain but in contrast to the theory construction was neither based on voluntary labour nor was it low cost. A bulldozer had been hired and was working under the guidance of one of the professional staff, an agricultural engineer. About 21 km of track had been created. In one valley three routes had been carved out of the wheatfields: two had quickly become waterlogged, a third at the side of the valley was just passable. Higher up the pass one stretch of 3 km had an average gradient of 16 per cent (1:6.2), but in some places gradients were 30 per cent (1:3.3). There was much discussion amongst colleagues responsible for various other project programmes as to where the bulldozer should be working. The author recommended to the Field Director that the bulldozer should be immediately sent off site until a coherent programme be developed. This was for the following reasons :

a) the visible product of the bulldozer's activity was neither low cost nor usable;

b) there was no plan of operation nor was equipment available to carry out the necessary back-up operations, particularly drainage and surfacing; equally, delays were anticipated in equipment supply and difficulties with regard to maintenance;
c) there was no map of the mountain route nor had any reconnaissance survey been carried out to establish preliminary routes or levels;
d) the spring rains were torrential; and the terrain soft sandstone: besides being idle during the rain, any work carried out by the bulldozer resulted, with each storm, in a morass. The work being carried out would have to be redone in the dry season. At the same time the higher reaches of track had become extremely dangerous to traverse;
e) as all the work being done by the D6 could be carried out manually, the money being spent on it could be used for hiring labour.

There were other reasons for a postponement of the road-building programme. While endogenous self-help is a noble idea and a case may be made for certain types of road building based on these principles, there were apparent constraints to the immediate implementation of such a programme. Firstly, in the face of visible evidence of the amount of money at the project's disposal (both in relation to the size of the staff and the vehicles imported), the local people were somewhat bemused at the need for ongoing voluntary labour on their part. Secondly, this attitude was exacerbated by evidence of the ready availability of equipment for construction. Equally, throughout the region it was frequently voiced that nowadays roads were built using machines (in particular bulldozers) and not men. Thirdly, neither the people nor project colleagues were unanimous as to the routes and types of road required. In sum, insufficient time and energy had been devoted to the careful pre-planning necessary to ensure the success of a self-help road-building project. However, there were two reasons why the bulldozer could not be returned. Firstly, a deposit of 50,000 tomans ($7,150) had been made for the D6. So far the bulldozer had not carried out 50,000 tomans of work. It was feared that should the bulldozer be returned the project would not be able to claim the balance from the equipment contractor.

Secondly, the bulldozer provided visible evidence that the project was active.

This, then, was the background to the initiation and implementation of labour-based road-building programme.

3. Social, environmental and technical factors

We now turn to a consideration of the various ways in which the standard of the road required by the project, a social decision, was affected by technical considerations and the environmental conditions of Alashtar. The method by which the road was to be built, voluntary participation, was affected firstly by the nature of the product required to fulfil the expected standard, and secondly by cultural factors. We will also show how interpretations of the theory of endogenous development made by professional colleagues and a certain bias in favour of machines militated against the adoption of a paid labour-based programme. At the same time the existing state of data on the relative merits of labour-and capital-intensive construction did not provide incontrovertible evidence of the technical efficiency of labour. Thus, in the face of opposition to any form of work using paid labour, it was not possible to present a clear-cut case for the adoption of a paid labour-based programme founded on its technical efficiency. Finally, we suggest the social factors which led to the eventual adoption of a paid labour-based programme.

3.1 *The standard of the road*

It has been mentioned above that the project was intent upon building low-cost minor roads.

Several environmental and technical factors suggested that the standard of road required for all-weather traffic was somewhat higher than that so far achieved through voluntary participation or the use of the D6. These factors included the following: the severe climatic conditions; the susceptibility of the terrain to these climatic conditions; the frequency of the cross-drainage necessitated by the existing irrigation system; the volume of tractor traffic and the destructive effect of tractors upon the existing tracks; the results of the traffic survey which showed that the new road would carry over 100 vehicles per day.

After consideration of the standard required — an all-

weather road — it was concluded that the road should be built as close to secondary standards as the lack of planing allowed. On the basis of this assessment and the poor quality of the work that had been carried out previously, it was contended that just running a bulldozer through would neither provide an all-weather route for commercial traffic nor, in the long run, would it be low cost[4].

3.2 *The method of construction*

a) *Voluntary participation* — We have seen above that one of the major objectives of the project was to foster self-reliance through the means of voluntary participation. It was therefore expected that low-cost roads should also be built using voluntary participation. It was agreed that improved maintenance would result: villagers would be acquainted with the techniques of construction and proud of their work, therefore they would be able and willing to perform maintenance operations.

It became clear that the theory conflicted with reality. Firstly, whatever the level of socio-economic conditions prevailing in the region, the scale of voluntary participation expected of the people seemed to be high. Initially it had appeared reasonable that one might expect sporadic co-operation from the villagers in relation to certain village or personal amenities. But from the outset it seemed unreasonable to expect anything to be built by voluntary labour that was either time-consuming or that did not directly affect a particular village.

Secondly, the lack of response by the people to the calls for voluntary participation was not aided by the lack of enthusiasm amongst many of the project trainees themselves. This was in part the result of the fact that two of the three trainee groups were derived essentially from the better-educated and wealthy in the Alashtar region. Anthropological work[5] has shown that, amongst the better-educated and wealthy of Alashtar, manual labour is considered to be undignified: the project trainees were averse to implementing that part of the theory which emphasised the role of manual labour.

Further, remarks of the people concerning the project indicated that at a very basic level a lack of appreciation existed amongst them as to its purpose. The activities of the professional staff were interpreted as "All those engineers just eat

and sleep and drive up and down in landrovers". And in relation to moral exhortations to participate voluntarily: "Those engineers get paid for not doing any work so why should I work and not get paid?" or "The project is part of the Government and the Government has lots of money so why should I work for nothing?". In addition, the project's concentration upon the need for voluntary work was interpreted as an attempt by the Government to foist third-class goods upon an unsuspecting public.

More fundamentally, the lack of voluntary participation reflected socio-economic characteristics. The low level of rural income in Lorestan is partly the result of seasonal unemployment. The climate of North and South-Western Iran (including Lorestan) is such that there is a slack period of six months in agriculture and at least four months in construction. The active periods for two of the major sources for earning income overlap. In Alashtar the intensive cycle of wheat, beans and sugarbeet means that during the best building weather agricultural activity is in progress. During the good weather, if other work is not available locally, those not employed in agriculture go to the cities, mostly to Teheran construction sites. However, the building season in Teheran is similar to that the Lorestan. During the long off-season unless workers migrate south there is very little work available and thus seasonal unemployment is high. While it is not possible to find data for Lorestan which clearly support such a commonly expressed criterion of visible underemployment/seasonal unemployment, a recent report concluded that, out of the 3.8 million agricultural workers in Iran, about 1 million "may thus be potentially unemployed, while those reported as seasonally unemployed are mainly landless labourers probably working much less than 100 days a year"[6].

Further to the short span of time available to accrue income, anthropological work in Lorestan[7], supported by other work in Iran[8], suggested that the vast majority of peasants were in debt to village headmen, local princes (Khans), or usurers. Thus, within the constraints of a low average income, the short span of time available for productive work, debt and social mores, there was little room for altruism during the best building weather.

There were therefore various socio-economic constraints upon the acceptance of the need for voluntary participation.

The theory of low-cost construction based upon voluntary participation conflicted with reality in the actual mode of operation. This was because expensive machinery had been hired without any coherent programme of operation. It was also proposed that further equipment be either bought or hired (graders, bulldozers, rollers, trucks). Voluntary labour was to complement equipment. However, the existing mode of operation and the equipment contemplated suggested that either construction would prove expensive or it would require inordinate amounts of voluntary labour.

The prevailing socio-economic conditions and the apparent need for employment creation were such that it was necessary to question whether most of the budget should be spent on buying or hiring of equipment or whether the funds might form the basis for an employment-creation programme. The title of the project suggested that it should include employment creation.

Socio-economic conditions indicated not only that extensive voluntary participation would not be possible but that there was a need for additional sources of income-generating employment in the region. The scale of funds at the project's disposal indicated that it possessed the resources to fulfil such a need. Consideration was therefore given to the role that might be played by a road-building programme based on paid labour.

b) *Technical efficiency of labour* — A feasibility study using the available literature was carried out. The results are summarised in tables 1-4. They show that for bulk excavation by labour, estimates vary from 0.12 m^3/hr to 2.28 m^3/hr (1,900 per cent variation) and for a D7 bulldozer from 64 m^3/hr to 410 m^3/hr (640 per cent variation).

Several utilisation rates were considered in calculating the cost of substitution of labour for equipment. For a utilisation rate of 2,500 hours per year, at a bulldozer cost of 32,600t/month ($4,650), the possible spectrum for substitution varies from 29.1 men costing 14,500t/month ($2,080) to 7,120 men costing 3,560,000t/month ($509,000).

Taking the figures at face value it was not possible to reach

any conclusion in favour of labour at market prices. Equally, whereas the literature produced by the ILO is cautiously optimistic about the technical efficiency of labour substitution[9], the IBRD consider that modifications have to be made to existing techniques in order to make the substitution of labour for machines competitive[10]. However, certain factors suggested that the higher ranges of equipment productivity and utilisation rates would not apply in Alashtar. The project lacked maintenance facilities capable of ensuring high utilisation of equipment. Further, without continual supervision it was not possible to authenticate the amount of work carried out by the bulldozer. Moreover, in a situation where optimum planning did not prevail, it would be impossible to keep the dozer continually active. However, in the case of a hired machine such inactivity would have to be paid for by the project. Thus for various reasons it was considered that the utilisation rates would be lower than optimum.

Such reasoning led to the following interpretation of the data: for a utilisation rate of 1,500 hrs/yr, at a low- to middle-range labour productivity of 0.82 m^3/hr, and the lower order of bulldozer productivities, the following might apply: 48.8 men costing 24,400t/month ($3,490), 91.5 men at 45,700t/month ($6,530) or 109.5 men at 54,700t/month ($7,815) would be equivalent to a D7 bulldozer costing between 30,000 and 33,000t/month ($4,280 to $4,720).

The proposal that an experimental paid labour-based programme should be initiated was based upon the following factors:

i) the role which could be played by a paid labour-based programme in regional employment creation;
ii) the flexibility of labour as opposed to machinery in particular the bulldozer;
iii) the heavy capital costs of equipment and the equally heavy, though somewhat milder, costs of maintenance;
iv) Muller's contention that the use of labour-based methods had also resulted in improved maintenance because of a greater feeling of involvement[11];
v) a case could be made for the technical efficiency of labour when compared with capital-intensive work.

c) *Voluntary labour v. paid labour v. equipment* — The proposal met with severe opposition. Firstly, it was widely held

that the payment of labour conflicted with the basic premises of the project. Secondly, it was held that the productivity of men could not possibly compete with that of machines ... in particular the bulldozer[12]. The caveats presented as to long-term maintenance costs of equipment and average efficiency were received sceptically.

Repeated experiences in connection with the bulldozer led to the conclusion that both local people and the project staff were almost in awe of the machine. Time and time again the villagers approached the project for the use of the bulldozer for activities which were totally beyond its ability. It appeared that one reason for the mainfest belief in the all-powerfulness of the bulldozer lay in its representation of modernity. To have work done by a bulldozer was the modern way of doing things.

Secondly, whereas the virtues of voluntary labour were declaimed, it was equally maintained that labour could not possibly compete with machines in respect of productivity. Paid labour was not only in contradiction to theory but more expensive and retrogressive as well. Voluntary labour in the context of a large equipment component was not.

The proposal that a labour-based programme be undertaken was therefore rejected out of hand on two basic grounds: paid labour was not in accordance with the theory of endogenous development and men could not compete with machines.

d) *Voluntary v. paid labour* — The project pressed ahead with road building by voluntary participation. Two factors resulted in the eventual adoption of an experimental programme using paid labour. The most important being the fact that, despite repeated attempts to recruit volunteers, no volunteers presented themselves. In addition, the employment that could be created for the money involved was pointed out, viz:

i) A full programme of capital-intensive work would utilise about 11,000t/day ($1,575). Implementing a programme where only 56 per cent of the cost was spent on labour would release 6,160t/day ($832) for their employment. At the current rate of 20t/day ($2.86) this would be sufficient to hire 308 people;

ii) the money presently spent upon the bulldozer alone could provide employment for 1,920/20 = 91 men per day.

The authorities were impressed by the sheer numbers of people who could be employed for the same amount of money as that being expended for the hiring of equipment. In the face of the continued lack of volunteers and the real need for visible product, they were sympathetic to the other arguments which had been put forward to support the initiation of an experimental programme of paid labour-based road construction. The combination of these factors caused the authorities to advocate the initiation of such a programme.

4. Summary of work programme and comment

4.1 *The work programme*

The programme consisted of the use of a combination of labour-based and equipment-intensive methods in the construction of some 15 kms of road over a 9-month period.

Detailed evaluations were made of the work completed (see table 5), the equipment and labour employed, the total costs and the various productivities for the following activities: embankment, gravelling, bridges and irrigation canal crossings. It must be pointed out that the size of staff did not permit accurate observation of quantities. The calculations were based on the daily reports compiled by the timekeeper and the head foreman, modified by observations made by the author.

4.2 *Comment on work completed*

First we will deal with aspects of the work which are to some extent quantifiable.

a) It was calculated that the productivity of labour for work which was considered in the feasibility study to be "excavate and load", varied from 3.44 to 3.8 m^3/man-day. The work was carried out under task work conditions which amounted to a working day of six hours. This is in the low range of labour productivities as derived from various sources and presented in table 4 (at this end of this chapter)[13].

b) The productivity of the D155A-1 (320 hp) bulldozer was found to vary as follows:
bulk excavation: (haul $<$ 20 m) : 105 m^3/hr; (average haul 50 m) : 42 m^3/hr;
excavate and shape embankment: (haul $<$ 20 m) : 41.7-67 m^3/hr.

These results vary from *3.6* to *9.1* per cent of the maximum manufacturer's productivities quoted in IBRD Technical Memorandum No. 7[14]. The productivity of the D6 (140 hp) for excavating and shaping the embankment (haul $<$ 20 m) was 27.5 m^3/hr or *5.5* per cent of the maximum quoted in Technical Memorandum No. 7[15]. Two points may be ventured in respect of the extremely low productivities obtained by the bulldozers. Firstly, the area adjacent to the route which was encroached upon during construction was five to ten times greater in the case of the bulldozer than in the case of labour. Secondly, the system of work employed by the dozer in making the embankment entailed a greater bulk movement of earth than that used by labour-based methods. The road was created by a series of movements entailing first the dumping of earth in large mounds followed by the shaping of these mounds into place.

c) It was possible to compare unit costs of labour and bulldozer for embankment construction. For labour this varied from 7 to 7.35t/m^3 (1 to 1.05\$$m^3$), whilst that for the bulldozer amounted to 3.83t/m[16]. At the rates charged for the bulldozer it can be seen that the labour-based work was distinctly inefficient: 83 to 92 per cent more expensive[17].

It must be stressed that the rate charged through the Governor General's office for a 320 HP bulldozer (D155A-1) was 140t/hr (\$20). The author has not been able to ascertain the market price of the same piece of equipment but the following comparisons may be made: from a rental contractor a "special price for the project" of a 270 hp (D8) had been 192t/hr (\$27.5/hr), the normal rate from the same contractor being 220t/hr (\$31.5/hr). By comparison with this rate it may be seen that the rate through the Governor General's office was generous, to say the least.

On the basis of rental contractors' rates for a D7 and a D8, the rate for a D155A-1 (320 hp) would be of the order of 265t/hr (37.90/hr). Using such a rate we find that the cost productivity of the bulldozer amounts to 6.83t/m^3 (\$0.98/m^3), i.e. *2.5* to *7.5* per cent cheaper than labour. Excluding the roller common to both we find the cost

productivity of the bulldozer amounts to 6.34t/m³, i.e. equipment becomes 3.1 to 3.6 per cent more expensive than labour. These estimates do not include transport costs (equivalent to two days' work). Thus, at prevailing market prices for the same piece of equipment, labour-intensive work becomes far more competitive than at the rates through the Governor General's office.

d) In the spreading operation, productivity amounted to 2.95 m³/man-day. However, it is felt that this productivity was severely inhibited by the frequent passage of trucks which disrupted the work.

e) The costs of gravel haulage amounted to 23 per cent of the cost (excluding river re-route and bridges).
Due to the loaders being supplied as part of the package from the Governor General's office, it was not possible to substitute labour for the loading process. Loading and haulage amounted to 28.4 per cent of the cost: at market prices this would amount to 32.5 per cent.

f) The method of constructing irrigation canal crossings based upon second-hand barrels was found to be satisfactory. The cost of one of these amounted to $147 as opposed to $345 using 45 cm diameter reinforced concrete pipes.

g) Self-driven vibrating rollers were bought in place of the tractor-drawn rollers specified. Not only were these vibrating rollers extremely sensitive — the smaller one was almost permanently out of action — but they could only travel on a level roadway which considerably restricted manoeuvreability.

h) Excluding the cost of re-routing the river and building the bridges, but including an estimate for completion of gravelling, the over-all cost per kilometre amounted to 105,500 tomans ($15,000). Using market rates for the hire of the bulldozer, trucks and loaders, the over-all cost per kilometre would have been 122,750 tomans ($17,525). These figures are well below contractors' estimates for similar standard roads in neighbouring areas, these being of the order of 200,000 to 230,000 tomans per kilometre ($28,600 to $32,800).

i) Tables 6 and 7 summarise the employment creation in man-days per kilometre for the different tasks and for

different combinations of the tasks. For the section of the road in which the embankment, spreading and water crossings were constructed by essentially labour-based means, the employment creation amounted to approximately 2,800 man-days per kilometre. For the section in which only spreading and water crossings were carried out by labour-based methods and the rest constructed by capital-intensive methods, the employment creation amounted to approximately 840 man-days per kilometre. It was possible to compare the costs per kilometre of construction of the whole road by the different methods, and the relative proportions of labour and equipment. Excluding overhead costs (salaried officials) a breakdown is given in table 5 and the results are summarised in table 8. The actual cost of the section in which embankment construction, water crossings and spreading were carried out by essentially labour-based means was 101,880 tomans per kilometre ($14,550). The actual cost of the section in which only spreading and water crossings were carried out by labour-based means and the rest was constructed by capital-intensive methods was 81,930 tomans per kilometre ($11,700).

We see that the actual cost of construction using a higher proportion of capital to labour was 19.5 per cent cheaper than that using nearly equal proportions of labour and capital. However, at market rates for equipment we find that the cost of the section which was constructed using a higher ratio of labour to capital would have amounted to 112,575 tomans per kilometre ($16,090), while the section constructed with a higher proportion of capital would have cost 113,175 tomans ($16,170). In this case, the section completed using a higher proportion of labour would have been 0.5 per cent cheaper.

Experience in the Alashtar programme also contributes to the less quantifiable aspects of the on-going debate as to the relative merits and demerits of labour-based and capital-intensive methods.

a) During the height of the agricultural season there was no difficulty in recruiting 100 men for the small labour-intensive programme. Later, when the workforce was

expanded, agricultural activity was still in progress. No difficulty was experienced in hiring 288 men.

By contrast, during the best building weather, there were often delays in the delivery of machinery. Therefore, in Alashtar, greater difficulty was experienced in locating machinery than men.

b) Some idea of the utilisation rates of equipment and the maintenance required has been given above. Mention should also be made of the repercussive effect that breakdowns had upon the work.

c) In Alashtar, when the programme or the weather changed, men could be laid off and recruited when necessary. By comparison, if one wished to lay off equipment for a short period, then one had to pay for the period laid off. If one wished to lay off equipment for a long period, then one could not be sure of being able to obtain it again on demand.

d) It has been suggested[18] that the ease of labour mobilisation and the lower overheads might be offset by the costs and organisational problems of running a large labour camp. In Alashtar this was not the case as the men were recruited from villages alongside the route. By contrast, it was found necessary to run a small road camp for the equipment operators and many difficulties were experienced in keeping them satisfied with the standard of food and accommodation.

It would seem therefore that for a small isolated programme without a rigorous work schedule (and limited workshop facilities), the hiring of machines is potentially more expensive than the hiring of men.

4.3 *Labour organisation*

The substitution of men for machines in Alashtar was facilitated by the fact that until abour 12 years ago, roads in Lorestan were built using labour as a major component. Many of the men were therefore familiar with the work.

Perhaps more important is that, in Alashtar, one of the forms of labour organisation is based upon gangleaders. Gangleaders find the work, supply the labour, and themselves supervise the working of the gang. As such, the reintroduction of labour-based work is not dependent upon extensive training

in labour organisation or the chance discovery of experienced foremen.

With a small staff it was necessary to promote workers who were willing and capable. It was found that unless care was taken to ensure that the delegation of authority was understood by all concerned (over 300 people), those to whom authority was delegated were unable to act. Conversely, once authority had been acknowledged, many of the new men were able to function very well.

Finally, while costs of labour mobilisation and overheads were very low, recruiting labour from villages along the route did result in a certain amount of friction as to who was entitled to work on a particular stretch of road.

5. **Conclusions**

5.1 *Conclusions related to technical aspects*

a) At the hiring rates available through the Governor General's office (almost half the market price), it was not possibie to achieve a technically efficient substitution of manual labour for machines. At market prices, however, estimates showed equipment-intensive methods to vary between 3.6 per cent more expensive and 7.5 per cent cheaper than labour-based methods.

b) Productivities for earthmoving equipment were found to be as low as 5 to 10 per cent of that of the maximum manufacturer's data quoted in the World Bank Technical Memoranda No. 7[19].

c) The variety of labour productivities presented in the literature was so varied that probably a month of work on site is necessary before an adequate estimate may be obtained for planning purposes.

d) In a small isolated community development project machine-intensive work is potentially more expensive than labour.

5.2 *Conclusions related to social aspects of the work*

a) Under the particular conditions obtaining in Alashtar, it was found difficult to introduce labour-based methods for the following reasons:

i) the professional staff were committed to the concept of voluntary work;
ii) the professional staff found it extremely difficult to accept that labour could be as technically efficient as machines;
iii) foremen tended to view labour-based work as giving them less status than equipment-intensive work;
iv) villagers and townspeople echoed professional staff opinion as to the manifold advantages of the bulldozer over labour. The villagers could see that the project had financial resources for equipment and consequently saw no necessity for *voluntary* labour-based methods of construction. The bias was removed once labour changed from voluntary to paid.

Under these conditions, it is considered that it is no more difficult to organise a labour-based work programme than any other civil engineering programme. If anything, the equipment side of the project provided more problems for the engineer.

b) Labour-based construction has often been seen to be particularly relevant to capital-scarce and labour-abundant economies. It might be argued that the material context of a capital-rich and rapidly modernising economy like Iran obviates the need for labour-based work. However, in Alashtar, the response to labour recruitment was such as to indicate that at the regional level an abundance of labour still exists. Within such a context the expansion of labour-based construction would be valid.

c) Seasonal variation of labour has often been seen as a restriction upon labour-based construction. Experience in Alashtar suggests that a quite substantial body of men could be hired for the whole building season. They could be employed in smaller teams to carry out particular parts of work scattered along the route — such as bridge construction, irrigation canal crossings and the more complicated pieces of embankment work.

d) Experience in Alashtar certainly substantiates the statements in the IBRD Phase I report that labour-based work should be "socially acceptable to the people of the country"[20].

Equally, that for labour-based work to be successful it should be "actively supported ... at the highest possible level"[21].

Notes and references

[1] The author wishes to acknowledge the significant roles played by the Field Director, Dr. M.T. Farvar (now Vice-Chancellor, Bu-Ali Sina University, Hamadan) and the Head Foreman, Mr. Shaverdi. Without their co-operation it would not have been possible to carry out the work described in this paper. He also wishes to thank Dr. G. Edmonds and Mr. P.A. Green for their assistance. Finally, he would like to thank Carol Gregor McCutcheon for her sustained interest through several drafts.

[2] For an overview of SIDP the reader is referred to M.T. Farvar and C. Razawi-Farvar, "The lessons of Lorestan, achievements and shortcomings of a project in endogenous development" *CERES* 9 (2), March-April 1976, pp. 44-47. In the present introduction the author has presented only the barest outline of the SIDP concentrating upon aspects pertinent to the road-building programme.

[3] The rial is the unit of currency in Iran. In 1977, 70 rials = $1. Colloquially the toman is used; 1 toman = 10 rials. The author has referred to tomans throughout the paper; 7 tomans = $1.

[4] The first 9 km of track originally created by the D6 had to be graded or dozed four times in as many months.

[14] "Productivity rates of earthmoving machines", Technical Memorandum No. 7 (IBRD, May 1975), p. 43.

[15] ibid., p. 42.

[16] Excluding the roller common to both methods, we find that labour varies from 6.12 to 6.15t/m^3 (0.875 to 0.878\$/m^3), while the bulldozer productivity amounts to 3.35t/m^3, i.e. 83 to 83.4 per cent more expensive. It is perhaps worth noting the obvious that the percentage of equipment cost increased with the decrease in the number of people employed to the detriment of labour cost productivities: for 120 men equipment was only 25.9 per cent of total costs, for 70 men it rose to 35.5 per cent.

EDITORS' SUMMARY

Whilst the studies and programmes executed, by the ILO and the World Bank in particular, have shown that labour-based methods are technically and economically viable, there is a natural reluctance, particularly on the part of engineers, to adopt their use. Robert McCutcheon's description of the project in Iran illustrates this point very well. The project staff clearly felt that labour-intensive methods were useful for self-help programmes which would encourage popular participation but not as effective alternatives to equipment. It is also fair to point out, in mitigation of this attitude, that previous experience with the use of labour-intensive methods particularly on major relief programmes, tended to support their basic assumption that these methods were neither technically nor economically effective. Whilst programmes such as that described by Glaister in Afghanistan are extremely useful in mobilising human resources and endeavour in the rural areas, their very nature is such that they are unlikely to be economically justifiable.

The reluctance of engineers to accept that labour-based methods are a viable technological alternative is most effectively overcome by demonstration. Recent work on appropriate construction technology has had many aspects, however, perhaps the most important single element has been the physical proof that labour-based methods can be used for a wide range of construction activities without any reduction in standard or increase in cost (whether measured in economic or financial terms). Furthermore, this conclusion has been reached not only from studies carried out in experimental conditions but also in fully operational construction projects. Nevertheless, the suggestion that we should think of these methods as feasible alternatives to the use of equipment rather than useful methods of providing employment and income does present other major problems. In the first place, it means

that their application has to be integrated into the institutional framework of the construction sector. It requires that the procedures and systems, developed principally for the use of equipment-intensive methods, have to be modified to incorporate the use of labour-based methods. This is well illustrated in Bertil Nilsson's paper, in particular in relation to training, procurement and administration.

Above all what emerges, in particular from the descriptions of the operational labour-based programmes, is *the need for commitment*. This is true whatever level is concerned. It is particularly vital that the government should be seen to be supporting the implementation of labour-based programmes: this not only confers respectability but should ensure that problems which will inevitably arise in their implementation receive sympathetic consideration. This could be reflected in the acceptance of tendering by specifications for hand tools, as in Kenya, or more broadly, in the endorsement of a programme by a senior politician, as in Iran.

At the other end of the scale there needs to be commitment at the grass-roots level. Unless the people themselves are convinced that the benefits of road construction will come to them, there is little likelihood of them being motivated to work effectively. The level of this popular participation can, of course, vary and leads logically to a socio-political discussion which is outside the scope of this book. However, there are clearly advantages and disadvantages whatever level is chosen. In Afghanistan, George Glaister found that where resources are extremely scarce there is great advantage in mobilising those of the rural population by giving them the responsibility for the selection and planning of work. However, there are serious disadvantages too, in that the people will only construct that which they feel is necessary and not that which might be necessary for safety and the type of traffic. In Mexico, on the other hand, whilst the people proposed and selected the roads, a contract was then made between the local community and the Direccion General de Caminos Rurales (DGCR) which ensured that the requisite number of labourers was available to construct a road whose standards were laid down by the DGCR. The basic difference, of course, between the Mexican and Afghanistan programmes is that in the former the labourers are paid whilst in

the latter they are not. This point is strongly made by McCutcheon. When the programme was based on self-help the villagers were unwilling to work for they could see that money was available to pay for machinery. When this money was utilised to pay labourers there was no difficulty in obtaining an adequate work force.

The move from equipment-intensive to labour-based methods therefore has ramifications outside the merely technical. Popular participation and commitment become important even in the decision-making process.

In his discussion of the private sector, Angus Austen also raises the question of commitment. If there is a real desire on the part of the government to develop the domestic construction sector then this implies a recognition of the biases in the procedures and systems against such development. He suggests that appropriate construction technology would be one means of allowing the small contractor to grow. The World Bank have also suggested that for certain countries to eliminate bias against the use of labour-based methods a "neutralisation" procedure could be adopted in the contractual process. This, of course, is a useful starting point but if labour-based methods are to achieve their full potential then the procedures and systems will have to be modified throughout so that a rational choice can be made by all involved in the construction process.

Even if the commitment exists, there still remains the detailed problems of modifying or reassessing all aspects of the construction process in relation to the application of labour-based methods. The main aspects of this are covered in Chapter 2. Nevertheless, they are reinforced by the evidence from the various programmes described. In relation to planning and administration it is interesting to compare the programmes in India, Kenya, Afghanistan and Mexico. The Border Roads Organisation is run on military lines and as such the hierarchy of responsibility is very clearly defined. It is also heavily centralised as the level of supervisory and administrative personnel indicates. At the other extreme, in the Afghanistan programme, the responsibility is devolved to the workers and the Rural Development Department officials act only as advisers not supervisors. The question of how far responsibility should be devolved depends on many factors

not least the nature of the programme. The Kenya Rural Access Roads Programme (RARP) covers the whole country and with such a dispersal of sites it is natural that the engineers in the field should have a large measure of responsibility. The same applies to the Mexican programme, however there is one basic difference. The RARP field structure is totally separated from that of the provincial engineer, who is the regional representative and executing agency of the Ministry of Works. Conversely, the Mexican programme is run through the field offices of the DGCR. The reasons for setting up specialised field units for the RARP are mainly to do with the shortage of qualified staff in the Ministry of Works provincial engineers offices and, perhaps more significantly, the fact that the RARP is, in large part, financed by external funds. The Mexican programme on the other hand is almost entirely financed by government funds. Whilst the Kenya RARP is proving to be a model for application elsewhere it would be more appropriate if such programmes were implemented within the structure of the public works ministry to ensure the involvement of its personnel. This would also be in line with the general philosophy that the use of labour-based methods should not be separated into a distinct programme, as if it were something of an oddity, but integrated into the framework of the operational ministries. This comes over clearly in Nilsson's paper. He strongly recommends that one should not set up separate systems of training, management administration and procurement for labour-based programmes, but modify and adapt the existing systems to allow their effective use. Glaister points out the Rural Development Department constructs tertiary roads on a self-help basis using labour-based methods whilst the Ministry of Public Works constructs primary and secondary roads using equipment. This division is not conducive to an acceptance within the Ministry of the use of labour-based methods. In fact it tends to reinforce the natural bias against their use on any projects except those constructed under relief programmes.

In the planning of a labour-based programe one of the major problems is in assessing the level of productivity that can be achieved. McCutcheon notes how difficult this was, not only because of lack of data, but because of the wide variations in that which does exist. What is clear is that the productivity

achieved on *traditional* labour-based schemes is grossly inferior to that on a well-organised, well-planned labour-based programme. Furthermore, motivation has a great deal to do with the level of productivity achieved. If the workers feel that the road they are constructing will be of direct benefit to them they are likely to achieve a reasonable level of productivity. This was clearly recognised in the Mexican programme. Moreover, whilst financial incentives do increase productivity this has to be viewed in relation to the present income and level of employment of the workers. In India and Kenya where the level of underemployment is high, the introduction of task rate working was sufficient to increase productivity. It is interesting to note that even in the self-help project on Afghanistan task work was introduced to increase productivity. .

Incentives and community spirit can increase productivity. However, innovations also have a role to play. Whilst the World Bank's view[1] is that the prospects of using "intermediate technologies" to improve productivity has been much overrated it is fair to point out that this conclusion is based on limited experience. Certainly the type of innovations made in the Philippines[2] can greatly increase the competitiveness of labour-based methods. Howe and Barwell's paper shows that there is a wide range of light equipment which could be developed effectively and that, to date, the amount of effort directed towards this aspect has been minimal when compared with the resources poured into the development of heavy construction equipment.

Little work has so far been done on the measurement of benefits that accrue through the use of labour-based methods in road construction. In general the benefits are assumed: increased employment, increased rural income, development of small-scale manufacturers, better access to markets and social services. Whilst this could be the subject of a book in itself, certain aspects are worth examining here.

Employment is the most obvious, direct benefit. The great majority of the workers hired on the various programmes discussed were hired on a casual basis. This was for various reasons: ease of administration, seasonal fluctuation of supply, the dispersed nature and limited length of the projects. "Casual" has, however, various interpretations. In the Border Roads Organisation the "casual labour" may have worked

with the BRO for years. In the Mexican Programme the average duration of employment was less than a month, whilst in Kenya 4-6 months is about average. Naturally, the shorter the duration the less is the benefit not only as regards income but also in terms of skill acquisition and physiological changes.

Even limited employment has substantial impact. The average increase of family income for workers on the Mexican programme was 15 per cent. Nevertheless, the ultimate object in the application of appropriate construction technology is a general increase in productive employment. It is perhaps a little unfair to criticise the programmes so far initiated for not providing more stable employment. They are isolated programmes, as yet, hopefully paving the way for a more general application. The criticism becomes somewhat cyclical. Appropriate construction technology must be adopted on a large scale in order to have an impact on employment. For this to happen demonstration projects must be set up which, by themselves, have little impact on employment.

The question of skill acquisition is perhaps more pertinent. In the long term, is one looking for underemployed workers to provide the basis of the workforce, or is one looking for the development of a construction labour force? Presumably the latter. However, this will take more time, even assuming that labour-based methods are implemented on a large scale both in the public and private sectors. What can be done now however is to ensure that there is a basis for the development of this labour force. This can be assisted by selecting from within the labour force those with management potential, for supervisor jobs. If appropriate construction technology achieves growing acceptance there will then be at least a cadre of people capable of implementing the work on the site. That some of those trained may choose to set up in business as private contractors should be viewed as a benefit not a loss. Angus Austen has shown that these people would have the means by which they could break out of the series of constraints that limit the development of the domestic construction sector.

The increase in income, particularly in the rural areas, should mean that more money is available for investment with a likely increase in agricultural production and rural industrial activities. However, there are constraints here. First the construction

of the rural road will not produce development, only the means by which it can take place. The complementary activities of extension services, social and welfare facilities must also take place. In this regard the construction of rural roads must be integrated into an over-all rural development framework for the expected benefits to take place. Second, as the Mexican programme has shown, the workers are generally the poorest of the population. The increase in income therefore allows them to rise up to or above the subsistence level, but not to the state where they can accumulate savings or use the money for increasing their agricultural yield. The people who benefited most from the Mexican programme were the rural elite, a minority no doubt, who could use the extra income for purchasing more land, better fertilisers or for planting a second crop. Nevertheless, the fact that 70 per cent of the investment in the Rural Access Roads Programme remains in the rural areas does indicate that this type of programme provides an effective means for initiating rural development.

One natural by-product of the use of labour-based methods is the need for a large number of good quality hand tools and light equipment. This presents an opportunity for the small-scale manufacturer to meet this demand and develop his business.

The essays in this book indicate the depth of knowledge already accumulated on the use of labour-based methods. They also show what still needs to be done.

Angus Austen's critical analysis of the problems facing the construction industry of developing countries shows clearly that we know very little about the sector of the economy within which one is proposing a modification of resource use. As he points out, in many countries the sector is not even recognised as a separate entity. Much more work needs to be done in defining the needs and basic statistics of the industry, so that effective programmes can be initiated for its development[3].

At the other end of the scale, it is clear that the work on tools and equipment has merely scratched the surface. Not only must the existing knowledge be catalogued (as in the forthcoming ILO *Guide to Tools and Equipment for Labour-Based Road Construction*) but also money must be invested in the development of tools and equipment.

We have talked a great deal about the need for commitment; however we have also recognised that "to see is to believe". Programmes like the Kenyan RARP provide a live demonstration of the viability of labour-based techniques. It will however be necessary to initiate more of these demonstration projects if engineers and policy makers are to be convinced.

Often information on new ideas tends to circulate among those who are already convinced of their rationality. The dissemination of information on the new ideas should really have two levels. First, what might be called propaganda material to policy makers to make them aware of the basic arguments. Second, detailed information to those who wish to attempt to implement the idea. McCutcheon makes a plea for a more concerted effort to provide specific information in a form which is immediately usable.

There has been recently a recognition of the need for construction management training. As Austen points out, however, it is vital that this type of training includes in it the presentation of the wide range of technologies available and the problems associated with the implementation of labour-based as well as equipment-based technologies.

Finally, transportation is a system of road and vehicle. To date the work on appropriate technology has concentrated on the road and its construction assuming that the vehicles that travel on them are the most appropriate. There is certainly a strong case to be made for the use of simpler vehicles, particularly in the rural areas, which are more in keeping with the needs and resources of the rural population[4].

There is now sufficient evidence both in the form of data and live projects, to show that labour-based methods are technically and economically viable. Many engineers are now taking the matter seriously. There are in-built prejudices which it will take time to change. However, the facts are there for those who care to see them. For policy makers and politicians the decision is less of a technical nature than one based upon broad socio-economic considerations. The use of labour-based methods would seem, however, to meet all the criteria upon which development planning is based. They serve the mass of the population, their implementation can involve popular participation in the decision-making process, they are

an instrument of self-reliance, they can enhance the potential for rural development and they can, by providing income, serve to improve the standard of living of the mass of the population. Why, one might ask, is their use not being implemented on a larger scale? The answer to that question is perhaps more political than rational. The means are available, what is now required is the will to use them.

Climbing Time

by Gary P. Joyce

I*f you think for a minute that one column can teach you to climb, you're out of your mind.* Get some lessons from a professional. Call the American Mountain Guide Association (303/271-0984) for a listing of guides in your area. Failing that, go to your local shop and ask for a referral. Don't figure you can do this by yourself unless you've got a death wish. That said, here's what you can expect if you decide to get involved in climbing. . .

Equipment

Start up costs aren't terrible; it's more a choice of what you want versus what you need. Essentials are: shoes, harness, locking carabiner, figure eight, belay device and chalk bag. This is assuming you'll find a partner (and finding a partner is one of the most difficult aspects of climbing) who has more cash than you and has already sprung for the rest of the gear.

If you've got a buddy who is also starting out, duplicate the above and add a rope, hardware, slings and more. Rock shoes have a sticky but smooth sole and rand and cost in the $100-$150 range; a harness should go about $40-$50; a locking biner about $10-$15, ditto with the figure eight, belay device and chalk bag (this holds gymnastic chalk).

The rope you use is specifically made for climbing- it has stretch in it, so when you fall (and you will fall) it'll give some. This type of rope is called a kernmantle rope; it has a braided outer sheath to protect the inner workings from abuse. Take care of your rope; don't step on it, don't tie the dog up with it, don't pull your car with it. Keep it out of the sun, don't store it in your trunk. Figure about $150 for a 50-meter dry (treated with water repellent) line.

Hardware is way too involved to go into here, but will cost you the biggest portion of cash. There're carabiners, camming devices, rocks, hexes and a zillion other combos. Budget about $500 for this for starters and figure on spending more as fast as you get better.

Ice gear is another story money-wise. If you purchased a fairly adjustable harness, you'll be able to use tha. Your rope will be fine, and so will your biners, belay devices and figure eight. Then tack on: two ice axes $350; plastic double boots $200-$400; crampons $150; helmet $50; hardware (ice screws, deadmen, etc.) $250; clothing $500 -$1200 depending on what you buy. (I swear by Gore-Tex and that ain't cheap. Don't forget, it's gonna be cold- and it can be wet.)

I have purchased climbing gear off the Internet at a substantial savings. I wouldn't buy a used rope or

carabiners, but just about anything else is a safe bet.

Terminology

Here are some words that'll make you sound like you know what you're talking about. . .

Free climbing - climbing with hands and feet; the rope is used only to hold a fall.
Solo climbing - climbing without a rope.
Bouldering - climbing, well, boulders. Usually unroped.
YDS - the Yosemite Decimal System. A rating system for climbs. It starts at 5.0 and goes to 5.14d. The letters come into play above 5.10. Climbing starts to get reeeeal hard above 5.9.
Lead climber - the climber going first.
Belay or belayer - The person holding the other end of the rope for the lead.
Second - the belayer and/or second climber up a route.
Top roping - how you'll learn to climb. The rope goes from a belayer on the ground up to an anchor and down to the climber. Routes are usually no more than 70 feet high.
Anchor - a fixed point above the climber the rope will run to and through.
Placement - where/how your hardware or protection (pro) is put into the rock on a free climb (non-top rope).
Rappelling - sliding down the ropes to return to where you started. More people get hurt doing this than in climbing. Pay mucho attention.
Pitch - the distance between belay points on any given climb. Limited to the length of your rope.
Carabiner or biner (beaner) -a oval or D-shaped piece of metal with a gate.

Getting Ready

At the lower levels of the rating system, and in your beginning days as a climber, you'll be able to overcome most difficulties with arm strength. This is a game in which legs are every bit as important as arms, though it will help if you have really strong forearms and fingers. I have one of those spring grips hanging from my rearview mirror and work out in sets of 50; I average about 200 per hand per day when I'm driving around.

Calf muscles are also important: do a lot of toe raises. Stand up on your toes and lower. No bouncing. To make it harder, do it on a raised platform so your heels can drop lower than your toes.

Eventually just about every other muscle in your body will come into play. You won't see any muscle-bound rock jocks, but you won't see any flab on any of them either. They're all cord, sinew and zero body fat. (I'm old, got a belly, shut up. I still climb.)
If you're hands aren't rough, they'll rip, and even rough hands tear on granite. They'll get used to it.

Moving

There are methods and means of foot and hand placement that vary according to medium (ice or rock) and what the rock (or ice) will give you. These are the things you'll learn from an instructor, so I won't go into it here. Here are some things to think about, however.

There's no room for ego when learning. Listen, do what you're told, ask questions, but keep your opinions to yourself; you're there to learn, and this is a serious game.
This is a thinking sport as well as a physical one. Use your mind when confronted with the "impossible."

Trust your foot gear. Rock shoes will stick if you use them right, as will crampons. Believe in your shoes.

Remember to make a concentrated effort to use your legs. You'll be surprised at what they'll do if you focus your power there.

When you "come off" (fall), try to come off in a controlled manner. You'll usually know it's going to happen and have time to say (yell?) to the belayer "falling" (honest). When you do come off, don't figure there's nothing else to do. You'll be going back into the face pretty much right away and you should be ready to absorb it. Slamming into things ain't fun.

Don't be afraid to improvise. When I was learning, I sort of shot it all about midway up the third pitch of a climb. There was a huge crack about shoulder level, so I jammed my arm in there elbow first and found I could rest almost all my weight on that arm. My instructor allowed how she'd never seen that maneuver before. It may not have been great form, but it worked.

Pro placement is a learned skill achieved by watching those more experienced than you, knowing the rock and knowing the limits of your hardware. Remember, if your placement fails you're now skydiving without a chute.

A word on helmets. When you're taking lessons, you'll have to wear one. Generally speaking, I rarely wear one when I climb rock (especially if I "know" the area). I always wear one on the ice, however. That said, a little piece of rock can attain a speed of 40-50 mph in about two seconds-think about getting conked with it.
Where To Go

Fortunately the Northeast is blessed with some great climbing areas. In New York you've got the famed Shawangunk Mountains (The Gunks) with zillions of routes, the Adirondacks for real wilderness/expedition-feeling climbing [article on the Gunks and the Dacks], the Delaware Water Gap area and more. Connecticut has the Traprock area, New Hampshire the White Mountains and Maine has Acadia National Park.

Then there are the climbing gyms which are springing up everywhere. These are great places to learn, work out and perfect technique, aren't weather dependent and provide a reasonable facsimile of real rock. There is a difference, however. You can perfect technique in a gym, but applying it to real-world rock starts another learning curve. The chances of getting hurt or killed in a gym are minimal to zero. The chances of getting hurt or killed on the rock aren't. They are two different mediums-as different as rock and ice. Don't think expertise in one, means expertise on the other.
Yes, it takes some work and takes some learning... but nothing beats sitting at the top of climb and looking down to the tops of trees as hawks and airplanes fly below you.

And to think, you got there all by yourself.

Rock climbing

From Wikipedia, the free encyclopedia

Rock climbing is an activity in which participants climb up, down or across natural rock formations or artificial rock walls. The goal is to reach the summit of a formation or the endpoint of a usually pre-defined route without falling. Due to the length and extended endurance required and because accidents are more likely to happen on descent than ascent, Rock Climbers do not usually climb back down the route. It is very rare for a climber to downclimb, especially on the larger multiple pitches (class III- IV and /or multi-day grades IV-VI climbs). Professional Rock climbing competitions have the objectives of either completing the route in the quickest possible time or attaining the farthest point on an increasingly difficult route. Scrambling, another activity involving the scaling of hills and similar formations, is similar to rock climbing. However, rock climbing is generally differentiated by its sustained use of hands to support the climber's weight as well as to provide balance.

A rock climber

Rock climbing is a physically and mentally demanding sport, one that often tests a climber's strength, endurance, agility and balance along with mental control. It can be a dangerous activity and knowledge of proper climbing techniques and usage of specialised climbing equipment is crucial for the safe completion of routes. Because of the wide range and variety of rock formations around the world, rock climbing has been separated into several different styles and sub-disciplines.[1]

History

Paintings dating from 200 BC show Chinese men rock climbing. In early America, the cliff-dwelling Anasazi in the 12th century were thought to be excellent climbers. Early European climbers used rock climbing techniques as a skill required to reach the summit in their mountaineering exploits. In the 1880s, European rock climbing become an independent pursuit outside of mountain climbing.[2]

Although rock climbing was an important component of Victorian mountaineering in the Alps, it is generally thought that the sport of rock climbing began in the last quarter of the nineteenth century in various parts of Europe. Rock climbing evolved gradually from an alpine necessity to a distinct athletic activity.

Aid climbing, climbing using equipment that acts as artificial handhold or footholds, became popular during the period 1920-1960, leading to ascents in the Alps and in Yosemite Valley that were considered impossible without such means. However, climbing techniques, equipment and ethical considerations have evolved steadily. Today, free climbing, climbing using holds made entirely of natural rock while using gear solely for protection and not for upward movement, is the most popular form of the sport. Free climbing has since been divided into several sub-styles of climbing dependent on belay configuration.

Over time, grading systems have also been created in order to compare more accurately the relative difficulties of the rock climbs.

Style

In *How to Rock Climb*, John Long notes that for moderately skilled climbers simply getting to the top of a route is not enough; how one gets to the top matters.[3] In rock climbing, style refers to the method of ascending the cliff. There are three main styles of climbing: on-sight, flash, and redpoint. To on-sight a route is to ascend the wall without aid or any foreknowledge. It is considered the way to climb with the most style. Flashing is similar to on-sighting, except that the climber has previous information about the route including talking about the beta with other climbers. Redpointing means to make a free ascent of the route after having first tried it.[4][5][6]

Climbing in Germany, circa 1965. Note the lack of intermediate protection points and the potentially unsafe tie-in method, which demonstrate the maxim of the day: "The leader must not fall."

Types of climbing

Most of the climbing done in modern times is considered free climbing—climbing using one's own physical strength, with equipment used solely as protection and not as support—as opposed to aid climbing, the gear-dependent form of climbing that was dominant in the sport's earlier days. Free climbing is typically divided into several styles that differ from one another depending on the choice of equipment used and the configurations of their belay, rope and anchor systems.

As routes get higher off the ground, the increased risk of life-threatening injuries necessitates additional safety measures. A variety of specialized climbing techniques and climbing equipment exists to provide that safety. Climbers will usually work in pairs and utilize a system of ropes and anchors designed to catch falls. Ropes and anchors can be configured in different ways to suit many styles of climbing, and roped climbing is thus divided into further sub-types that vary based on how their belay systems are set up. Generally speaking, beginners will start with top roping and/or easy bouldering and work their way up to lead climbing and beyond.

Aid climbing

Still the most popular method of climbing big walls, aid climbers make progress up a wall by repeatedly placing and weighting gear that is used directly to aid ascent and enhance safety.

Free climbing

The most commonly used method to ascend climbs refers to climbs where the climber's own physical strength and skill are relied on to accomplish the climb. Free climbing may rely on top rope belay systems, or on lead climbing to establish protection and the belay stations. Anchors, ropes and protection are used to back up the climber and are passive as opposed to active ascending aids. Subtypes of free climbing are trad climbing and sport climbing. Free climbing is generally done as "clean lead" meaning no pitons or pins are used as protection.[7]

Bouldering

Climbing on short, low routes without the use of the safety rope that is typical of most other styles. Protection, if used at all, typically consists of a cushioned bouldering pad below the route and a spotter, a person who watches from below and directs the fall of the climber away from hazardous areas. Bouldering may be an arena for intense and relatively safe competition, resulting in exceptionally high difficulty standards.

Bouldering in Joshua Tree National Park, United States.

Solo climbing

Deep-water soloing (DWS)

Deep-water soloing (or psicobloc) is similar to free soloing in that the climber is unprotected and without a rope, but should the climber fall, it is into deep water instead of onto the ground.

Free soloing

Free soloing, referred to as "soloing" in the UK, is single-person climbing without the use of any rope or protection system whatsoever. If a fall occurs and the climber is not over water (as in the case of deep water soloing), the climber is likely to be killed or seriously injured. Though technically similar to bouldering, free solo climbing typically refers to routes that are far taller and/or far more lethal than bouldering. The term "highball" is used to refer to climbing on the boundary between free soloing and bouldering, where what is usually climbed as a boulder problem may be high enough for a fall to cause serious injury (20 ft. and higher) and hence could also be considered to be a free solo.

Roped solo climbing

Solo climbing with a rope secured at the beginning of the climb allowing a climber to self-belay as they advance. Once the pitch is completed the soloist must descend the rope to retrieve their gear, and then reclimb the pitch. This form of climbing can be conducted free or as a form of aid climbing.

Lead climbing

Lead climbing is a climbing technique. The lead climber ascends with the rope passing through intermittent anchors that are below them, rather than through a top anchor, as in a top-roped climb. A partner belays from below the lead climber, by feeding out enough rope to allow upward progression without undue slack. As the leader progresses he or she clips the rope into, using a runner and carabiners, intermediate points of protection such as active cams, or passive protection such as nuts; this limits the length of a potential fall. The leader also may clip into pre-placed bolts. Indoor gyms might have short runners pre-attached to fixed anchor points in the wall.

Unlike top-rope climbing where the climber is always supported by an anchor located above the climber, lead climbing often has scenarios where the climber will be attached to a point under him or her. In these cases, if the climber were to fall, the distance fallen would be much greater than that of top-rope and this is one of the main reasons lead climbing can be dangerous. The fall factor is the ratio of the height a climbers falls and the length of rope available to absorb the fall. The higher the fall factor, the more force placed on the climber as the ropes decelerates them. The maximum fall factor is 2. It is often advised that climbers who are interested in lead climbing should learn from experienced climbers and participate in training sessions before actually lead climbing on their own.

Multi-pitch climbing

The climbing rope is of a fixed length; the climber can only climb the length of the rope. Routes longer than the rope length are broken up into several segments called pitches; this is known as multi-pitch climbing. At the top of a pitch, the leader, the first climber to ascend, sets up an anchor and then belays the second climber up to the anchor; as the second climber follows the route taken by the leader, the second climber removes (cleans) the carabiners and anchors placed along the way in order to use them again on the next pitch. Once both climbers are at the top anchor, the leader begins climbing the next pitch and so on until the top of the route is reached.

Leader belays the second on *Illusion Dweller* in Joshua Tree National Park, United States.

In either case, upon completion of a route, climbers can walk back down if an alternate descent path exists, or rappel (abseil) down with the rope.

Sport climbing

Unlike traditional rock climbing, sport climbing involves the use of protection (bolts) placed with power drills or on rappel or permanent anchors which are attached to the rock walls. This is separate from bolted trad face climbing.

Traditional climbing

Traditional or *trad* climbing involves rock climbing routes in which protection against falls is placed by the climber while ascending, or bolts placed on lead. Gear is used to protect against falls but not to aid the ascent directly. Traditional bolted face climbs are different than sport climbs. Trad bolted climbs use either a hand drill and or are bolted on lead. This means there are far fewer bolts and they are spaced out farther than sport climbs.

Bottom rope climbing and top rope climbing

Bottom rope climbing

Commonly known as "Top Roping": belaying a climber from the ground or the base of the route. A belay system resembling a pulley in which an anchor has been created at the top of a climb, through which the rope runs through from the belayer on the ground, to the climber on the ground *(position before starting the climb)*. The rope is "taken-in", to clear up the slack as the climber moves upwards, so in the event of a fall the climber falls the shortest distance possible. The length of a fall is normally no more than a meter, but can vary depending on the length of the route *(*the longer the rope, the more stretch the rope will undergo when weighted*)* and the weight of the climber compared to that of the belayer, among other things.

Top rope climbing

Also known as "seconding," or belaying a climber from the top of a route, bringing them up to walk off or continue on to next pitch. A similarly safe system of climbing a route, except the belayer has set the anchors at the top of the climb (normally after leading a route) to belay the climber either indirectly (belayer is part of the

system and can be vunlnerable when exposed to unexpected directions of pull and loading of the rope) or directly (belayer is not part of the system and belaying is done direct from the anchors using either an Italian / Munter Hitch or adapted use of a belay device), up the route from the top. If bolts have been clipped or traditional gear placements have been made, it is the job of the climber to collect and clean the route.

Top roping *Balthazar* (12), in the Morialta Conservation Park near Adelaide, South Australia. Top roping is the most accessible style of climbing for beginners.

Via ferrata

A method of fairly easily ascending a route, heavily dependent on permanent protection rather than using natural rock features to proceed.

Climbing techniques

Different types of rock require different techniques to successfully climb.

Crack climbing

Crack climbing is a type of rock climbing that ascends cracks and uses specialized climbing techniques. Cracks used in climbing vary in size from the width of a finger to those that fit an entire body. Climbers use techniques such as jamming, laybacking, and stemming. Some climbers use gloves made out of athletic tape to protect their hands.

climber with climbing aids attached at his waist

Face climbing

Face climbing is a type of climbing where climbers use features and irregularities in the rock such as finger pockets and edges to ascend a vertical rock face.

Slab climbing

Slab climbing is a type of rock climbing where the rock face is at an angle of less steep than vertical. It is characterized by balance- and friction-dependent moves on very small holds.

Simul climbing

When two climbers move at the same time. The pseudo-lead climber places gear that the pseudo-follower collects. When the leader runs low on gear they construct a belay station where the follower can join them to exchange gear. The stronger climber is often the pseudo-follower since a fall by the follower would pull the leader from below towards the last piece of gear—a potential devastating fall for the leader. In contrast, a fall from the leader would pull the follower from above, resulting in a less serious fall. Most speed ascents involve some form of simul climbing but may also include sections of standard free climbing and the use of placed gear for advancement (i.e. partial aid or pulling on gear).

Via ferrata

A method of fairly easily ascending a route, heavily dependent on permanent protection rather than using natural rock features to proceed.

Grading systems

Climbing communities in many countries and regions have developed their own rating systems for routes. Ratings, or grades, record and communicate consensus appraisals of difficulty. Systems of ratings are inherently subjective in nature, and variation of difficulty can be seen between two climbs of the same grade. Hence, there may be occasional disagreements arising from physiological or stylistic differences among climbers. The practice of rating a climb below its actual difficulty is known as sandbagging.

The most commonly used rating systems in the United States are the Yosemite Decimal System and the Hueco V-scale bouldering grade. The current ranges for climbing routes are 5.0 for easy beginner routes to 5.15 being world class and V0 - V16, respectively. As the limit of human climbing ability has not yet been reached, neither grading system has a definite endpoint and is thus subject to revision.[8]

The ratings take into account multiple factors affecting a route, such as the slope of the ascent, the quantity and quality of available handholds, the distance between holds, ease of placing protection and whether advanced technical maneuvers are required. Typically the rating for the hardest move on the wall will be the rating for the whole climb. While height of a route is generally not considered a factor, a long series of sustained hard moves will often merit a higher grade than a single move of the same technical difficulty. For example, a climb with multiple 5.11 moves with no rests may thus be rated a 5.12.

ROCK CLIMBING RATING SYSTEMS

	Sierra (USA)	British (UK)		French	UIAA (Central Europe)	Austr-alian	GDR (Eastern Europe)

Extreme	5.14d	7c		9a	11+		

Climbing grades simplified. There are many other grades but these are the most used.

Terminology

As climbing routes or problems increase in difficulty, climbers learn to develop skills that help them complete the climbs clean. There are several techniques for hands and feet as well as terms for motions that combine the two. For indoor gyms, route setters visualize and create routes for climbers, placing different kinds of holds in specific parts of the wall at particular angles because they intend climbers to use certain techniques.

Environments

Indoor climbing

Indoor climbing occurs in buildings on artificial rock structures. This permits for climbing in all types of weather and at all times of day. Climbers climb indoors to improve their skills and techniques, as well as for general exercise or fun. Indoor climbing gyms typically provide rope setups and ensure that new climbers know safe techniques.

Outdoor climbing

Outdoors, climbs usually take place on sunny days when the holds are dry and provide the best grip, but climbers can also attempt to climb at night or in adverse weather conditions if they have the proper training and equipment. However, night climbing or climbing in adverse weather conditions will increase the difficulty and danger on any climbing route.

An indoor climbing wall.

Equipment

Most climbers choose to wear specialized rubber climbing shoes which are often of a smaller size than their normal street shoes in order to improve sensitivity towards foot placements and use the tightness to their advantage. Climbing chalk ($MgCO_3$) is commonly used as a drying agent to minimize sweating of the hands. Most other equipment is of a protective nature. Rock climbing is inherently dangerous, so to minimize the potential consequences resulting from a fall, climbers use protection. The most basic protective equipment is a climbing rope. Climbing pioneers would attach the rope to themselves; in the event of a fall, the rope would usually cause injury to the climber in the hope that it prevented death. With advances in technology came the development of specialized harnesses, carabiners which are used for clipping into belay and rappel anchors and connecting gear, and belay devices which are used to catch a falling climber, hold or lower a climber and for rappelling. Eventually, the placement of bolts with the use of quickdraws led to the rise of sport climbing. Traditional climbers developed the spring-loaded camming device, which increased safety over chocks, hexes, and pitons. Some climbers choose to wear a specialized climbing helmet to protect them from falling rocks or equipment or head injuries from crashing into rocks.[9]

Injuries

Injuries in rock climbing are mainly sports injuries that occur due to falls or overuse. Injuries due to falls are relatively uncommon; the vast majority of injuries result from overuse, most often occurring in the fingers, elbows, and shoulders.[10] Such injuries are often no worse than torn calluses, cuts, burns and bruises. There are a number of skincare products specifically for climbers available in the market. However, overuse symptoms, if ignored, may lead to permanent damage especially to tendons, tendon sheaths, ligaments, and capsules. Injuries from lead climbing are common.

Planning your climb, knowing your partner, talking about your climb, checking your equipment and the conditions of the rocks, checking the weather, using good judgement and always paying attention minimize the risk of injury.[11]

Access to climbing areas

Indigenous culture considerations

Some areas that are popular for climbing, for example in the United States and Australia, are also sacred places for indigenous peoples. Many such indigenous people would prefer that climbers not climb these sacred places and have made this information well known to climbers. A well-known example is the rock formation that Americans have named Devils Tower National Monument.[12] Native American cultural concerns also led to

complete climbing closures at Cave Rock at Lake Tahoe,[13] Monument Valley, Shiprock and Canyon de Chelly.[14]

Climbing activities can sometimes encroach on rock art sites created by various Native American cultures and early European explorers and settlers. The potential threat to these resources has led to climbing restrictions and closures in places like Hueco Tanks, Texas,[15] and portions of City of Rocks National Reserve, Idaho.

In Australia, the monolith Uluru (Ayers Rock) is sacred to local indigenous communities and climbing is banned on anything but the established ascent route (and even then climbing is discouraged).

Indigenous peoples are not the only cultures that object to climbing on certain rock formations. Professional climber Dean Potter kicked off a major controversy when he ignored long-accepted convention to scale Delicate Arch in 2006, resulting in strict new climbing regulation in Arches National Park.[16]

Climbing on private property

Many significant rock outcrops exist on private land. Some people within the rock climbing community have been guilty of trespassing in many cases, often after land ownership transfers and previous access permission is withdrawn. In the U.S. the climbing community responded to access closures by forming the Access Fund. This is an "advocacy organization that keeps U.S. climbing areas open and conserves the climbing environment. Five core programs support the mission on national and local levels: public policy, stewardship and conservation (including grants), grassroots activism, climber education and land acquisition."[17] In the U.K. the British Mountaineering Council represents climbers and their interest of public access to crags, cliffs and boulders.

Environmental impact

Although many climbers adhere to "minimal impact" and "leave no trace" practices, rock climbing is sometimes damaging to the environment. Common environmental damages include: soil erosion, breaking rock features, chalk accumulation, litter, abandoned bolts and ropes, human excrement, introduction of foreign plants through seeds on shoes and clothing, as well as damage to native plant species (especially those growing in cracks and on ledges as these are often intentionally removed during new route development through a process commonly referred to as *cleaning)*.

Clean climbing is a style of rock climbing which seeks to minimize some of the aesthetically damaging side effects of some techniques used in trad climbing and more often, aid climbing by avoiding using equipment such as pitons, which damage rock.

Climbing can also interfere with raptor nesting, since the two activities often take place on the same precipitous cliffs. Many climbing area land managers institute nesting season closures of cliffs known to be used by protected birds of prey like eagles, falcons and osprey.[18]

Many non-climbers also object to the appearance of climbing chalk marks, anchors, bolts and slings on visible cliffs. Since these features are small, visual impacts can be mitigated through the selection of neutral, rock-matching colors for bolt hangers, webbing and chalk. The use of certain types of climbing gear is banned altogether at some crags due to the risk of damage to the rock face. In such cases, climbers use knotted slings and ropes for climbing protection.

Blowtorching is another climbing induced impact that effects the rocks themselves. Blowtorching is when a

climber uses a blowtorch to dry holds on a wet route. This mainly happens in areas that tend to have wet climbing conditions. Blowtorching is not only detrimental to the rock itself and can have permanent damage but it also leaves a very large burn mark that most non-climbers would object to the appearance of.

Vandalism

The most significant form of vandalism directly attributable to rock climbers is alteration of the climbing surface to render it more climber-friendly.

With the advent of hard, bolted sport climbing in the 1980s, many routes were "chipped" and "glued" to provide additional features, allowing them to be climbed at the standard of the day. This attitude quickly changed as the safer sport climbing technique allowed climbers to push hard without much risk, causing the formerly more-or-less fixed grades to steadily rise. Altering routes began to be seen as limiting and pointless.

Unlike traditional climbing which generally uses protection only as a backup in case of falls, some forms of climbing—like sport climbing, canyoneering or, especially, aid climbing—rely heavily on artificial protection to advance, either by frequent falls or by directly pulling on the gear. Often these types of climbing involve multiple drilled holes in which to place temporary bolts and rivets, but in recent years an emphasis on clean techniques has grown.

Today, the charge of vandalism in climbing is more often a disagreement about the appropriateness of drilling and placing permanent bolts and other anchors. Although new fixed anchors are rarely placed by climbers, their dependency on the existing fixed anchors results in the difference between life and death. But the existing anchors remain on the climbing structure for long periods of time, changing the dynamic of the structure itself. Due to the permanent impact of the fixed anchors in wilderness areas, it was prohibited by the Wilderness Act. However, in 1990, there was a movement by the Forest Service and the Task Group to change the regulations to where fixed anchors would be allowed but still regulated in wilderness areas. These improvements lead to protection for both the climbers and the Wilderness Act.[19] Typically in the USA, the first ascensionists decide where to place protection on a new route and later climbers are supposed to live with these choices. This can cause friction and retro-bolting when the route is perceived to be dangerous to climbers who actually lead at the grade of the climb, since the first ascensionists often lead at a higher grade and therefore don't require as much protection. Failing to properly design a new route at its grade is considered arrogant and very poor form. Even in strongholds of rock-climbing tradition like Yosemite National Park, many routes are being gradually upgraded to safer standards of protection.

Rock-climbing equipment

From Wikipedia, the free encyclopedia

A wide range of equipment is used during rock or any other type of climbing. The most popular types of climbing equipment are briefly described in this article. The article on protecting a climb describes equipment commonly used to protect a climber against the consequences of a fall.[1]

Rope, cord and webbing

Rope and climber's shoes

Climbing ropes are typically of kernmantle construction, consisting of a core (kern) of long twisted fibres and an outer sheath (mantle) of woven coloured fibres. The core provides about 80% of the tensile strength, while the sheath is a durable layer that protects the core and gives the rope desirable handling characteristics.

Ropes used for climbing can be divided into two classes: dynamic ropes and low elongation ropes (sometimes called "static" ropes). Dynamic ropes are designed to absorb the energy of a falling climber, and are usually used as Belaying ropes. When a climber falls, the rope stretches, reducing the maximum force experienced by the climber, their belayer, and equipment. Low elongation ropes stretch much less, and are usually used in anchoring systems. They are also used for abseiling (rappelling) and as fixed ropes climbed with ascenders.

Modern webbing or "tape" is made of nylon or Spectra/Dyneema, or a combination of the two. Climbing-specific nylon webbing is generally tubular webbing, that is, it is a tube of nylon pressed flat. It is very strong, generally rated in excess of 9 kN, or about 2,020 pounds of force. Dyneema is even stronger, often rated above 20 kN (about 4,500 lbf or 2000 kg) and as high as 27 kN (about 6,070 lbf or 2700 kg). In 2010, UK-based DMM performed fall factor 1 and 2 tests on various Dyneema and Nylon webbings, showing Dyneema slings can fail even under 60 cm falls. Tying knots in Dyneema webbing was proven to have reduced the total amount of supported force by as much as half.[2]

When webbing is sewn or tied together at the ends, it becomes a sling or runner, and if you clip a carabiner to each end of the sling, you have a quickdraw. These loops are made one of two ways—sewn (using reinforced stitching) or tied. Both ways of forming runners have advantages and drawbacks, and it is for the individual climber to choose which to use. Generally speaking, most climbers carry a few of both types. It is also important to note that only nylon can be safely knotted into a runner (usually using a water knot or beer knot), Dyneema is always sewn because the fibers are too slippery to hold a knot under weight.

Webbing has many uses such as:

- Extending the distance between protection and a tie-in point.
- An anchor around a tree or rock.
- An anchor extension or equalization.
- Makeshift harnesses.
- Carrying equipment (clipped to a sling worn over the shoulder).
- Protecting a rope that hangs over a sharp edge (tubular webbing).

Carabiners

Carabiners are metal loops with spring-loaded gates (openings), used as connectors. Once made primarily from steel, almost all carabiners for recreational climbing are now made from a light weight aluminum alloy. Steel carabiners are much heavier, but harder wearing, and therefore are often used by instructors when working with groups.

Carabiners exist in various forms; the shape of the carabiner and the type of gate varies according to the use for

which it is intended. There are two major varieties: locking and non-locking carabiners. Locking carabiners offer a method of preventing the gate from opening when in use. Locking carabiners are used for important connections, such as at the anchor point or a belay device. There are several different types of locking carabiners, including a twist-lock and a thread-lock. Twist-lock carabiners are commonly referred to as "auto-locking carabiners" due to their spring-loaded locking mechanism. Non-locking carabiners are commonly found as a component of quickdraws.

Carabiners are made with many different types of gates including wire-gate, bent-gate, and straight-gate. The different gates have different strengths and uses. Most locking carabiners utilize a straight-gate. Bent-gate and wire-gate carabiners are usually found on the rope-end of quickdraws, as they facilitate easier rope clipping than straight-gate carabiners.

Carabiners are also known by many slang names including *biner* (pronounced beaner) or *Krab*.

The first climber who used a carabiner for climbing was German climber Otto Herzog.[3]

The Maillon (or Maillon Rapide) performs a similar function to a carabiner but instead of a hinge has an internally threaded sleeve engaging with threads on each end of the link, and is available in various shapes and sizes. They are very strong but more difficult to open, either deliberately or accidentally, so are used for links which do not need to be released during normal use, such as the center of a harness.

Quickdraws

Quickdraws (often referred to as "draws") are used by climbers to connect ropes to bolt anchors, or to other traditional protection, allowing the rope to move through the anchoring system with minimal friction. A quickdraw consists of two non-locking carabiners connected together by a short, pre-sewn loop of webbing. Alternatively, and quite regularly, the pre-sewn webbing is replaced by a sling of the above-mentioned dyneema/nylon webbing. This is usually of a 60 cm loop and can be tripled over between the carabiners to form a 20 cm loop. Then when more length is needed the sling can be turned back into a 60 cm loop offering more versatility than a pre-sewn loop. Carabiners used for clipping into the protection generally have a straight gate, decreasing the possibility of the carabiner accidentally unclipping from the protection. The carabiner into which the rope is clipped often has a bent gate, so that clipping the rope into this carabiner can be done quickly and easily. Quickdraws are also frequently used in indoor lead climbing. The quickdraw may be pre-attached to the wall. When a climber ascends the wall, (s)he must clip the rope through the quickdraw in order to maintain safety. The safest, easiest and most effective place to clip into a quickdraw is when it is at waist height.

Harnesses

A harness is a system used for connecting the rope to the climber. There are two loops at the front of the harness where the climber ties into the rope at the working end using a figure-eight knot. Most harnesses used in climbing are preconstructed and are worn around the pelvis and hips, although other types are used occasionally. Usually young children use a full body harness because it gives more support for the body.

Different types of climbing warrant particular features for harnesses. Sport climbers typically use minimalistic harnesses, some with sewn-on gear loops. Alpine climbers often choose lightweight harnesses, perhaps with

detachable leg loops. Big Wall climbers generally prefer padded waist belts and leg loops. There are also full body harnesses for children, whose pelvises may be too narrow to support a standard harness safely. These harnesses prevent children from falling even when inverted, and are either manufactured for children or constructed out of webbing. Some climbers use full body harnesses when there is a chance of inverting, or when carrying a heavy bag. There are also chest harnesses, which are used only in combination with a sit harness; this combination provides the same advantages as a full body harness. However, test results from UIAA show that chest harnesses can put more impact on the neck than sit harnesses, making them slightly more dangerous to use.

Apart from these harnesses, there are also caving and canyoning harnesses, which all serve different purposes. For example, a caving harness is made of tough waterproof and unpadded material, with dual attachment points. Releasing the maillon from these attachment points loosens the harness quickly.

Canyoning harnesses are somewhat like climbing harnesses, often without the padding, but with a seat protector, making it more comfortable to rappel. These usually have a single attachment point of Dyneema.

Belay devices

Belay devices are mechanical friction brake devices used to control a rope when belaying. Their main purpose is to allow the rope to be locked off with minimal effort to arrest a climber's fall. Multiple kinds of belay devices exist, some of which may additionally be used as descenders for controlled descent on a rope, as in abseiling or rappelling.

ATC-XP on locking carabiner

Belay devices are available in both passive and active designs:

Passive belay devices rely on the belayer's brake hand and a carabiner to lock off the rope. Sticht plates and the Air Traffic Controller (ATC) line of belay devices by Black Diamond Equipment are examples of passive belay devices. If a belay device is lost or damaged, a Munter hitch on a carabiner can be used as an improvised passive belay device.

Active belay devices have a built-in mechanism that locks off the rope without the help of any other pieces of equipment. The GriGri by Petzl is an example of an active belay device. The offset cam in the GriGri locks off the rope automatically to catch a falling climber, much like a seat belt in a car locks off to hold a passenger securely.

However, the GriGri's automatic action can lead to less alert belayers. The GriGri is not a hands-free belay device and constant vigilance is required by the belayer no matter what kind of device is used. One common mistake with the GriGri is reverse threading it, rendering the camming action useless.[4] Though, in a fall with a reverse threaded GriGri, bending the rope sharply under the GriGri provides more than enough friction to hold a falling climber as long as the belayer locks off the rope as they would with a tube style (passive) device.

It's important to note that in the event of a fall, automatic belay devices place more force on the anchors so are better suited for sports/indoor climbing. Most only work with thick single ropes, and they are not as versatile as other devices.[5]

An example of traditional belay is the Body Belay or the Hip Belay, where the rope is wrapped around the body to provide enough friction to catch a climber. This is often used in Alpine climbing where efficiency is important.

Rappel devices (descenders)

These devices are friction brakes which are designed for descending ropes. Many belay devices can be used as descenders, but there are descenders that are not practical for belaying, since it is too difficult to feed rope through them, or because they do not provide sufficient friction to hold a hard fall.

Figure eight

Sometimes called "figure of eight" or just "eight", this device is most commonly used as a descender, but may also be used as a belay device in the absence of more appropriate equipment.

It is an aluminum or steel "8" shaped device, but comes in several varieties. Its main advantage is efficient heat dissipation. A square eight, used in rescue applications, is better for rappelling than the traditional 8.

Figure eights allow fast but controlled descent on a rope. They are easy to set up and are effective in dissipating the heat caused by friction but can have a tendency to cause a rope to twist. Holding the brake hand off to the side twists the rope, whereas holding the brake hand straight down, parallel to the body, allows a controlled descent without twisting the rope. An 8 descender can wear a rope more quickly than a tube style belay/rappel device because of the many bends it puts into the rope. Many sport climbers also avoid them because of the extra bulk a Figure 8 puts on the climbing rack. However, many ice climbers prefer to use the 8, because it is much easier to thread with stiff or frozen rope.

A figure eight descender

Rescue eight

A rescue eight is a variation of a figure eight, with "ears" or "wings" which prevent the rope from "locking up" or creating a larks head or girth hitch, thus stranding the rappeller on the rope. Rescue eights are frequently made of steel, rather than aluminum.

Rescue eight

Petzl Pirana

The Petzl Pirana is a slight variation to the traditional Figure 8 rappel device. The Pirana consists of a single loop of metal with double prongs jutting out of the bottom. Designed primarily for canyoneering, the Pirana allows for a variety of friction modes and, therefore, lowering speeds.[6] The Pirana supports three different braking positions, each supplying a different amount of friction, thereby changing the lowering speed. In contrast to the Figure 8, the Pirana can be loaded or disconnected from the rope without having to be removed from the carabiner.

For comfort, the Pirana can be extended away from the climber with nylon webbing or with a number of locking carabiners.[7]

Rappel Rack

This consists of a 'U' shaped frame, attached to the rappeller's harness, into which snap multiple bars that pivot

from the other side of the frame. The rope is woven through as many of the bars as are required to provide sufficient friction. This arrangement allows for variations in rope diameter and condition, as well as controlled rate of descent. Racks are seldom used in sport climbing. Cavers often use racks on long rappels because friction can be adjusted by adding or removing bars.

Ascenders

Ascenders are mechanical devices for ascending on a rope. They are also called Jumars, after a popular brand.

Jumars perform the same functionality as friction knots but less effort is needed to use them. A Jumar employs a cam which allows the device to slide freely in one direction but tightly grip the rope when pulled on in the opposite direction. To prevent a jumar from accidentally coming off the rope, a locking carabiner is used. The Jumar is first attached to the climber's harness by a piece of webbing or sling, and then the Jumar is clipped onto the rope and locked. Two ascenders are normally used to climb a fixed rope. For climbing a fixed rope attached to snow anchors on a steep slope, only one Jumar is used as the other hand is used for holding the ice axe.

Another type of ascender allows rope to feed in either direction, slowly, but locks up when pulled quickly. Such self-locking devices allow people to protect solo climbs because the amount of rope is automatically adjusted.

Sling

A **sling** or **runner** is an item of climbing equipment consisting of a tied or sewn loop of webbing that can be wrapped around sections of rock, hitched (tied) to other pieces of equipment or even tied directly to a tensioned line using a prusik knot, for anchor extension (to reduce rope drag and for other purposes), equalisation, or climbing the rope.

Daisy chain

A daisy chain is a strap, several feet long and typically constructed from one-inch tubular nylon webbing of the same type used in lengthening straps between anchor-points and the main rope. The webbing is bar tacked at roughly two-inch intervals (or, in the past, tied) to create a length of small loops for attachment. Unlike the use of similar devices in backpacking, daisy chains in technical rock climbing are expected to be of sufficient strength to be "load bearing,". Daisy chain pockets however are not rated to full strength, and can only take static loads.

A daisy chain

When clipped in, daisy chains should not be shortened by clipping in another pocket to the same carabiner. Failure of the pocket stitching results in the daisy chain disconnecting from the anchor, with potentially fatal consequences. If shortening the daisy chain when clipped in, in order to eliminate dangerous slack, a second carabiner should be used to connect to the anchor.[8]

Though daisy chains are sometimes used by free climbers as a type of sling (a quick attachment used from harness directly to a belay anchor), and for ad hoc purposes similar to those of the backpacker, the canonical use for a daisy chain is in aid climbing, wherein the leader will typically attach one end to the harness, and the

other to the top-most anchor placement (by carabiner or fifi hook), particularly after having ascended in étriers as high as possible. This allows the leader to hang from the daisy chain while preparing the next anchor placement. The closely spaced loops allow fine-tuning the length from harness to anchor, thereby allowing the best possible reach for the next placement.

Daisy chains should not be confused with étriers, also known as *aiders*, which are short ladders made in the same way, but with larger loops, also used in aid climbing, nor with load-limiting devices often known as screamers (from their first trade name) designed to simulate a dynamic belay.

Protection devices

Protection devices, collectively known as *rock protection* or *pro*, provide the means to place temporary anchor points on the rock. These devices may be categorized as *passive* (e.g., nuts) or *active* (e.g., SLCDs). Passive protection acts "merely" as a choke when pulled on, and constrictions in the rock prevent it from pulling out. Active protection transforms a pull on the device into an outward pressure on the rock that helps the device set more firmly. The type of protection that is most appropriate varies depending on the nature of the rock.

Nuts

Typical nuts and a nut tool

Nuts are manufactured in many different varieties. In their simplest form, they are just a small block of metal attached to a loop of cord or wire. They are used by simply wedging them into narrowing cracks in the rock, then giving them a tug to set them. Nuts are sometimes referred to by the slang term, *wires*.

Black Diamond Hexcentrics

Hexes

Hexes are the oldest form of active protection. They consist of a hollow eccentric hexagonal prism with tapered ends, usually threaded with cord or webbing. They are frequently placed as a passive chock, but are more commonly placed in active camming positions. In the standard active placement, a fall causes the hex to twist in its placement exerting sideways force on the rock in which it is placed. They are manufactured by several firms, with a range of sizes varying from about 10mm thick to 100mm wide. Sides may be straight or curved.

Spring-loaded camming devices

These consist of three or four cams mounted on a common axle or two adjacent axles, in such a way that pulling on the shaft connected to the axle forces the cams to spread further apart. The SLCD is used like a syringe, by pulling the cams via a "trigger" (a small handle) which forces them closer, inserting it into a crack or pocket in the rock, and then releasing the trigger. The springs make the cams expand and grip the rock face securely. A climbing rope may then be attached to the end of the stem via a sling and carabiner. SLCDs are typically designed to maintain a constant camming angle with the rock to ensure that the normal force provided by the cam lobes against the rock face will supply enough friction to hold a cam in equilibrium with the

rock.[9]

An SLCD placed in a crack.

Tricams

A *Tricam* is a device that can be used as either active or passive protection. It consists of a shaped aluminium block attached to a length of tape (webbing). The block is shaped so that pulling on the tape makes it cam against the crack, gripping the rock tighter. Careful placement is necessary so that the "cam" does not loosen when not loaded. It is generally not as easy to place or remove as a SLCD but is much cheaper and lighter, and often is the only thing that will work in situations like quarry drill-holes and limestone pockets. The smaller sizes can work well in old piton scars, and can also be used passively as nuts.

Training equipment

Various items of equipment are employed during climbing-specific training.

Hangboards

A wooden or resin board used for improving contact strength for climbers. It develops the forearm muscles along with the tendons and pulleys of the fingers.

A wooden hangboard designed for increasing contact strength in rock climbers by Concept Climbing

They consist of a variety of different-sized pockets and edges that are designed to be hung from with various training protocols. These pockets and edges can range from large jug holds to micro crimp edges. When used effectively they can facilitate huge gains in forearm strength and lock off strength, mostly in the flexor digitorum profundus and flexor digitorum superficialis muscles of the fore arms. They are also an apparatus with the capability to injure the user, usually in the A1-4 pulleys or along sections of flexor carpi sheath linking the different FDS or FDP sections in the forearm.

Hangboards are the best way to increase contact strength for rock climbers, and when following a well established training protocol such as Eva Lopez's max weight min edge program, tremendous gains in strength can be made over the long term. Training is usually done in cycles.

Hangboards are usually mounted above a doorway, or anywhere that allows the user's body to hang freely, one of the best available attachment areas is to roof beams. They are also called fingerboards.

Grip savers

A small device that can help in developing the antagonist muscles to those used while gripping with the hand. Use of such a device can prevent the ligament injuries that are frequently experienced by climbers.

Campus boards

A series of horizontal rungs attached to an overhanging surface that may be climbed up and down without the

aid of the feet. When used properly, campus boards can improve finger strength and so-called "contact strength".

Bachar ladder

A bachar ladder is made by stringing large diameter PVC piping on webbing and is climbed without using the feet. It can help improve overall upper body strength as well as core strength.

Specialized clothing

In the early days of climbing, many would have considered specialised clothing to be cheating. In fact, the first climbers considered an untucked shirt or unbuttoned sport jacket a sign of weakness. Several climbers even chose to climb barefoot, an act that modern climbers would find amazing. In the 1980s and early 1990s, the trend was to wear tight, brightly coloured clothes often made from Spandex. The trend, now, is to wear looser-fitting clothing. Trousers can be tailored to prevent them from restricting movement by adding features such as articulated knee joints and diamond crotch.

Helmet

Black Diamond Equipment Half Dome climbing helmet

The climbing helmet is a piece of safety equipment that primarily protects the skull against falling debris (such as rocks or dropped pieces of protection) and impact forces during a fall. For example, if a lead climber allows the rope to wrap behind an ankle, a fall can flip the climber over and consequently impact the back of the head. Furthermore, any effects of pendulum from a fall that have not been compensated for by the belayer may also result in head injury to the climber. The risk of head injury to a falling climber can be further significantly mitigated by falling correctly.

A Petzl Elios climbing helmet designed for caving and mountaineering

Climbers may decide whether to wear a helmet based on a number of factors such as the type of climb being attempted, concerns about weight, reductions in agility, added encumbrances, or simple vanity. Additionally, there is less incentive to wear a helmet in artificial climbing environments like indoor climbing walls (where routes and holds are regularly maintained) than on natural multi-pitch routes or ice climbing routes (where falling rocks and/or ice are likely).

Climbing shoes

Specifically designed foot wear is usually worn for climbing. To increase the grip of the foot on a climbing wall or rock face due to friction, the shoe is soled with a vulcanized rubber layer. Usually, shoes are only a few millimetres thick and fit very snugly around the foot. Stiffer shoes are used for "edging", more compliant ones for "smearing". Some have foam padding on the heel to make descents and rappels more comfortable.

Climbing shoes can be re-soled which decreases the frequency that shoes need to be replaced.

Belay gloves

A belay glove is a glove constructed from either leather or a synthetic substitute, is used to protect the hands when belaying, and is especially useful if using a classic or body belay. They are also very useful for controlling the belay with single, lead ropes that are 9.5 mm or smaller.[10] Ultimately, belay gloves can lessen the possibility of rope burn and the subsequent involuntary release of the rope.

A Belay glove

Miscellaneous equipment

Tape

Medical tape is useful to both prevent and repair minor injuries. For example, tape is often used to fix flappers. Many climbers use tape to bind fingers or wrists to prevent recurring tendon problems. Tape is also highly desirable for protecting hands on climbing routes that consist mostly of repeated hand jamming.

"Tape" can also refer to nylon webbing.

Haul bag

A haul bag refers to a large, tough, and often unwieldy bag into which supplies and climbing equipment can be thrown. A rucksack or day pack often has a webbing, haul loop on the top edge.

Haul bags are often affectionately known as "pigs" due to their unwieldy nature.

Gear sling

A gear sling is usually used by trad (traditional), or big wall climbers when they have too much gear to fit onto the gear loops of their harnesses. The simplest forms are homemade slings of webbing; more elaborate forms are padded.

Chalk

Chalk is used by nearly all climbers to absorb problematic moisture, often sweat, on the hands. Typically, chalk is stored as a loose powder in a special chalk bag designed to prevent spillage, most often closed with a drawstring. This chalk bag is then hung by a carabiner from the climbing harness or from a simple belt worn around the climber's waist . This allows the climber to re-chalk during the climb with minimal interruption or effort. To prevent excess chalking (which can actually *decrease* friction), some climbers will store their chalk in a chalk ball, which is then kept in the chalk bag. A chalk ball is a very fine, mesh sack that allows chalk release with minimum leakage when squeezed so that the climber can control the amount of chalk on the hands.

Chalk is most frequently white, and the repeated use of holds by freshly-chalked hands leads to chalky build-up. While this isn't a concern in an indoor gym setting, white chalk build-up on the natural rock of

outdoor climbs is considered to be an eyesore at best, and many consider it a legitimate environmental/conservation concern. In the United States, the Bureau of Land Management advocates the use of chalk that matches the color of the native rock.[11] Several popular climbing areas, like Arches National Park have banned white chalk, instead allowing the use of rock-colored chalk. Garden of the Gods has gone further, banning the use of calcium carbonate (the most common chalk) outright, requiring the use of a rock-colored substitute. A handful of companies make colored chalk or a chalk substitute designed to comply with these environmental conservation measures.

Rocket

From Wikipedia, the free encyclopedia

A Soyuz-U, at Baikonur cosmodrome's Site 1/5 in Kazakhstan

A **rocket** (from Italian *rocchetto* "bobbin")[nb 1][1] is a missile, spacecraft, aircraft or other vehicle that obtains thrust from a rocket engine. Rocket engine exhaust is formed entirely from propellant carried within the rocket before use.[2] Rocket engines work by action and reaction and push rockets forward simply by expelling their exhaust in the opposite direction at high speed, and can therefore work in the vacuum of space.

In fact, rockets work more efficiently in space than in an atmosphere. Multi-stage rockets are capable of attaining escape velocity from Earth and therefore can achieve unlimited maximum altitude. Compared with airbreathing engines, rockets are lightweight and powerful and capable of generating large accelerations. To control their flight, rockets rely on momentum, airfoils, auxiliary reaction engines, gimballed thrust, momentum wheels, deflection of the exhaust stream, propellant flow, spin, and/or gravity.

Rockets for military and recreational uses date back to at least 13th century China.[3] Significant scientific, interplanetary and industrial use did not occur until the 20th century, when rocketry was the enabling technology for the Space Age, including setting foot on the moon. Rockets are now used for fireworks, weaponry, ejection seats, launch vehicles for artificial satellites, human spaceflight, and space exploration.

Chemical rockets are the most common type of high power rocket, typically creating a high speed exhaust by the combustion of fuel with an oxidizer. The stored propellant can be a simple pressurized gas or a single liquid fuel that disassociates in the presence of a catalyst (monopropellants), two liquids that spontaneously react on contact (hypergolic propellants), two liquids that must be ignited to react, a solid combination of fuel with oxidizer (solid fuel), or solid fuel with liquid oxidizer (hybrid propellant system). Chemical rockets store a large amount of energy in an easily released form, and can be very dangerous. However, careful design, testing, construction and use minimizes risks.

History

The first gunpowder-powered rockets were developed in Song China, by the 13th century. The Chinese rocket technology was adopted by the Mongols and the invention was spread via the Mongol invasions to the Near East and Europe in the mid 13th century.[4] Medieval and early modern rockets were used militarily as incendiary weapons in sieges.

An early Chinese text to mention the use of rockets was the *Huolongjing*, written by the Chinese artillery officer Jiao Yu in the mid-14th century. Between 1270 and 1280, Hasan al-Rammah wrote *al-furusiyyah wa al-manasib al-harbiyya* (*The Book of Military Horsemanship and Ingenious War Devices*), which included 107 gunpowder recipes, 22 of which are for rockets.[5][6] In Europe, Konrad Kyeser described rockets in his military treatise *Bellifortis* around 1405.[7]

Drawing of a Chinese soldier lighting a rocket's fuse (1890)

Depiction of a rocket (1405)

William Congreve at the bombardment of Copenhagen (1807)

The name *Rocket* comes from the Italian *rocchetta*, meaning "bobbin" or "little spindle", given due to the similarity in shape to the bobbin or spool used to hold the thread to be fed to a spinning wheel. The Italian term was adopted into German in the mid 16th century by Leonhard Fronsperger and Conrad Haas, and by the early 17th century into English.[1] *Artis Magnae Artilleriae pars prima*, an important early modern work on rocket artillery, by Kazimierz Siemienowicz, was first printed in Amsterdam in 1650.

The first iron-cased rockets were developed in the late 18th century in the Kingdom of Mysore, adopted and improved as the Congreve rocket and used in the Napoleonic Wars. The first mathematical treatment of the dynamics of rocket propulsion is due to William Moore (1813). In 1815, Alexander Dmitrievich Zasyadko constructed rocket-launching platforms, which allowed rockets to be fired in salvos (6 rockets at a time), and gun-laying devices. William Hale in 1844 greatly increased the accuracy of rocket artillery. The Congreve rocket was further improved by Edward Mounier Boxer in 1865.

Konstantin Tsiolkovsky (1903) first speculated on the possibility of manned spaceflight with rocket technology. Robert Goddard in 1920 published proposed improvements to rocket technology in *A Method of Reaching Extreme Altitudes*. In 1923, Hermann Oberth (1894–1989) published *Die Rakete zu den Planetenräumen* ("The Rocket into Planetary Space")

Modern rockets originated when Goddard attached a supersonic (de Laval) nozzle to the combustion chamber of a liquid-fueled rocket engine. These nozzles turn the hot gas from the combustion chamber into a cooler, hypersonic, highly directed jet of gas, more than doubling the thrust and raising the engine efficiency from 2% to 64%. Use of liquid propellants instead of gunpowder greatly improved the effectiveness of rocket artillery in World War II, and opened up the possibility of manned spaceflight after 1945.

In 1943, production of the V-2 rocket began in Germany. In parallel with the guided missile programme, rockets were also used on aircraft, either for assisting horizontal take-off (RATO), vertical take-off (Bachem Ba 349 "Natter") or for powering them (Me 163, see list of World War II guided missiles of Germany). The Allies' rocket programs were less sophisticated, relying mostly on unguided missiles like the Soviet Katyusha rocket. The Americans captured a large number of German rocket scientists, including Wernher von Braun, and brought them to the United States as part of Operation Paperclip. After the war, rockets were used to study high-altitude conditions, by radio telemetry of temperature and pressure of the atmosphere, detection of cosmic rays, and further research; notably the Bell X-1, the first manned vehicle to break the sound barrier. Independently, in the Soviet Union's space program research continued under the leadership of the chief

Goddard with a liquid oxygen-gasoline rocket (1926)

designer Sergei Korolev.

During the Cold War, rockets became extremely important militarily as modern intercontinental ballistic missiles (ICBMs). The 1960s became the decade of rapid development of rocket technology particularly in the Soviet Union (Vostok, Soyuz, Proton) and in the United States (e.g. the X-15). Rockets were now used for space exploration, with the American manned programs Project Mercury, Project Gemini and later the Apollo programme culminated in 1969 with the first manned landing on the moon via the Saturn V.

Types

Vehicle configurations

Rocket vehicles are often constructed in the archetypal tall thin "rocket" shape that takes off vertically, but there are actually many different types of rockets including:[8][9]

Saturn V is the biggest rocket to have successfully flown.

- tiny models such as balloon rockets, water rockets, skyrockets or small solid rockets that can be purchased at a hobby store
- missiles
- space rockets such as the enormous Saturn V used for the Apollo program
- rocket cars
- rocket bike[10]
- rocket-powered aircraft (including rocket assisted takeoff of conventional aircraft- RATO)
- rocket sleds
- rocket trains
- rocket torpedoes[11][12]
- rocket-powered jet packs[13]
- rapid escape systems such as ejection seats and launch escape systems
- space probes

Launch of *Apollo 15* Saturn V rocket: $T - 30$ s through $T + 40$ s

Design

A rocket design can be as simple as a cardboard tube filled with black powder, but to make an efficient, accurate rocket or missile involves overcoming a number of difficult problems. The main difficulties include cooling the combustion chamber, pumping the fuel (in the case of a liquid fuel), and controlling and correcting the direction of motion.[14]

Components

Rockets consist of a propellant, a place to put propellant (such as a propellant tank), and a nozzle. They may also have one or more rocket engines, directional stabilization device(s) (such as fins, vernier engines or engine gimbals for thrust vectoring, gyroscopes) and a structure (typically monocoque) to hold these components together. Rockets intended for high speed atmospheric use also have an aerodynamic fairing such as a nose cone, which usually holds the payload.[15]

As well as these components, rockets can have any number of other components, such as wings (rocketplanes), parachutes, wheels (rocket cars), even, in a sense, a person (rocket belt). Vehicles frequently possess navigation systems and guidance systems that typically use satellite navigation and inertial navigation systems.

Engines

Viking 5C rocket engine

Rocket engines employ the principle of jet propulsion.[2] The rocket engines powering rockets come in a great variety of different types; a comprehensive list can be found in rocket engine. Most current rockets are chemically powered rockets (usually internal combustion engines,[16] but some employ a decomposing monopropellant) that emit a hot exhaust gas. A rocket engine can use gas propellants, solid propellant, liquid propellant, or a hybrid mixture of both solid and liquid. Some rockets use heat or pressure that is supplied from a source other than the chemical reaction of propellant(s), such as steam rockets, solar thermal rockets, nuclear thermal rocket engines or simple pressurized rockets such as water rocket or cold gas thrusters. With combustive propellants a chemical reaction is initiated between the fuel and the oxidizer in the combustion chamber, and the resultant hot gases accelerate out of a rocket engine nozzle (or nozzles) at the rearward-facing end of the rocket. The acceleration of these gases through the engine exerts force ("thrust") on the combustion chamber and nozzle, propelling the vehicle (according to Newton's Third Law). This actually happens because the force (pressure times area) on the combustion chamber wall is unbalanced by the nozzle opening; this is not the case in any other direction. The shape of the nozzle also generates force by directing the exhaust gas along the axis of the rocket.[2]

Propellant

Rocket propellant is mass that is stored, usually in some form of propellant tank or casing, prior to being used as the propulsive mass that is ejected from a rocket engine in the form of a fluid jet to produce thrust.[2] For chemical rockets often the propellants are a fuel such as liquid hydrogen or kerosene burned with an oxidizer such as liquid oxygen or nitric acid to produce large volumes of very hot gas. The oxidiser is either kept separate and mixed in the combustion chamber, or comes premixed, as with solid rockets.

Sometimes the propellant is not burned but still undergoes a chemical reaction, and can be a 'monopropellant' such as hydrazine, nitrous oxide or hydrogen peroxide that can be catalytically decomposed to hot gas.

Gas Core light bulb

Alternatively, an inert propellant can be used that can be externally heated, such as in steam rocket, solar thermal rocket or nuclear thermal rockets.[2]

For smaller, low performance rockets such as attitude control thrusters where high performance is less necessary, a pressurised fluid is used as propellant that simply escapes the spacecraft through a propelling nozzle.[2]

Uses

Rockets or other similar reaction devices carrying their own propellant must be used when there is no other substance (land, water, or air) or force (gravity, magnetism, light) that a vehicle may usefully employ for propulsion, such as in space. In these circumstances, it is necessary to carry all the propellant to be used.

However, they are also useful in other situations:

Military

Some military weapons use rockets to propel warheads to their targets. A rocket and its payload together are generally referred to as a *missile* when the weapon has a guidance system (not all missiles use rocket engines, some use other engines such as jets) or as a *rocket* if it is unguided. Anti-tank and anti-aircraft missiles use rocket engines to engage targets at high speed at a range of several miles, while intercontinental ballistic missiles can be used to deliver multiple nuclear warheads from thousands of miles, and anti-ballistic missiles try to stop them. Rockets have also been tested for reconnaissance, such as the Ping-Pong rocket, which was launched to surveil enemy targets, however, recon rockets have never come into wide use in the military.

A Trident II missile launched from sea.

Science and research

Sounding rockets are commonly used to carry instruments that take readings from 50 kilometers (31 mi) to 1,500 kilometers (930 mi) above the surface of the Earth.[17]

Rocket engines are also used to propel rocket sleds along a rail at extremely high speed. The world record for this is Mach 8.5.[18]

Spaceflight

Larger rockets are normally launched from a launch pad that provides stable support until a few seconds after ignition. Due to their high exhaust velocity—2,500 to 4,500 m/s (9,000 to 16,200 km/h; 5,600 to 10,100 mph)—rockets are particularly useful when very high speeds are required, such as orbital speed at

approximately 7,800 m/s (28,000 km/h; 17,000 mph). Spacecraft delivered into orbital trajectories become artificial satellites, which are used for many commercial purposes. Indeed, rockets remain the only way to launch spacecraft into orbit and beyond.[19] They are also used to rapidly accelerate spacecraft when they change orbits or de-orbit for landing. Also, a rocket may be used to soften a hard parachute landing immediately before touchdown (see retrorocket).

A Bumper sounding rocket

Rescue

Apollo LES pad abort test with boilerplate crew module.

Rockets were used to propel a line to a stricken ship so that a Breeches buoy can be used to rescue those on board. Rockets are also used to launch emergency flares.

Some crewed rockets, notably the Saturn V[20] and Soyuz[21] have launch escape systems. This is a small, usually solid rocket that is capable of pulling the crewed capsule away from the main vehicle towards safety at a moments notice. These types of systems have been operated several times, both in testing and in flight, and operated correctly each time.

This was the case when the Safety Assurance System (Soviet nomenclature) successfully pulled away the L3 capsule during three of the four failed launches of the Soviet moon rocket, N1 vehicles 3L, 5L and 7L. In all three cases the capsule, albeit unmanned, was saved from destruction. It should be noted that only the three aforementioned N1 rockets had functional Safety Assurance Systems. The outstanding vehicle, 6L, had dummy upper stages and therefore no escape system giving the N1 booster a 100% success rate for egress from a failed launch.[22][23][24][25]

A successful escape of a manned capsule occurred when Soyuz T-10, on a mission to the Salyut 7 space station, exploded on the pad.[26]

Solid rocket propelled ejection seats are used in many military aircraft to propel crew away to safety from a vehicle when flight control is lost.[27]

Hobby, sport, and entertainment

Hobbyists build and fly a wide variety of model rockets. Many companies produce model rocket kits and parts but due to their inherent simplicity some hobbyists have been known to make rockets out of almost anything. Rockets are also used in some types of consumer and professional fireworks. A Water Powered Rocket is a type of model rocket using water as its reaction mass. The pressure vessel (the engine of the rocket) is usually a used plastic soft drink bottle. The water is forced out by a pressurized gas, typically compressed air. It is an example of Newton's third law of motion.

The scale of amateur rocketry can range from a small rocket launched in your own backyard to a rocket that reached space.[28] Amateur rocketry is split into three categories: low power, mid power, and high power.

Australia, Austria, Canada, Germany, New Zealand, Switzerland, the United Kingdom, and the United States

have high power rocket associations which provide certifications to its members to fly different rocket motor sizes. While joining these organizations is not a requirement, they often provide insurance and flight waivers for their members.

Hydrogen peroxide rockets are used to power jet packs,[29] and have been used to power cars and a rocket car holds the all time (albeit unofficial) drag racing record.[30]

Corpulent Stump is the most powerful non commercial rocket ever launched on an Aerotech engine in the United Kingdom.

Noise

Rocket exhaust generates a significant amount of acoustic energy. As the supersonic exhaust collides with the ambient air, shock waves are formed. The sound intensity from these shock waves depends on the size of the rocket as well as the exhaust velocity. The sound intensity of large, high performance rockets could potentially kill at close range.[31]

Workers and media witness the Water Sound Suppression System test at Launch Pad 39A.

The Space Shuttle generates 180 dB of noise around its base.[32] To combat this, NASA developed a sound suppression system which can flow water at rates up to 900,000 gallons per minute (57 m^3/s) onto the launch pad. The water reduces the noise level from 180 dB down to 142 dB (the design requirement is 145 dB).[33] Without the sound suppression system, acoustic waves reflect off of the launch pad towards the rocket, vibrating the sensitive payload and crew. These acoustic waves can be so severe that they can destroy the rocket.

A Saturn V launch was detectable on seismometers a considerable distance from the launch site.

Noise is generally most intense when a rocket is close to the ground, since the noise from the engines radiates up away from the jet, as well as reflecting off the ground. This noise can be reduced somewhat by flame trenches with roofs, by water injection around the jet and by deflecting the jet at an angle.[31]

For crewed rockets various methods are used to reduce the sound intensity for the passengers, and typically the placement of the astronauts far away from the rocket engines helps significantly. For the passengers and crew, when a vehicle goes supersonic the sound cuts off as the sound waves are no longer able to keep up with the vehicle.[31]

Physics

Operation

The effect of the combustion of propellant in the rocket engine is to increase the velocity of the resulting gases to very high speeds, hence producing a thrust. Initially, the gases of combustion are sent in every direction, but only those that produce a net thrust have any effect. The ideal direction of motion of the exhaust is in the direction so as to cause thrust. At the top end of the combustion chamber the hot, energetic gas fluid cannot move forward, and so, it pushes upward against the top of the rocket engine's combustion chamber. As the combustion gases approach the exit of the combustion chamber, they increase in speed. The effect of the convergent part of the rocket engine nozzle on the high pressure fluid of combustion gases, is to cause the gases to accelerate to high speed. The higher the speed of the gases, the lower the pressure of the gas (Bernoulli's principle or conservation of energy) acting on that part of the combustion chamber. In a properly designed engine, the flow will reach Mach 1 at the throat of the nozzle. At which point the speed of the flow increases. Beyond the throat of the nozzle, a bell shaped expansion part of the engine allows the gases that are expanding to push against that part of the rocket engine. Thus, the bell part of the nozzle gives additional thrust. Simply expressed, for every action there is an equal and opposite reaction, according to Newton's third law with the result that the exiting gases produce the reaction of a force on the rocket causing it to accelerate the rocket.[34][nb 2]

A balloon with a tapering nozzle. In this case, the nozzle itself does not push the balloon but is pulled by it. A convergent/divergent nozzle would be better.

In a closed chamber, the pressures are equal in each direction and no acceleration occurs. If an opening is provided in the bottom of the chamber then the pressure is no longer acting on the missing section. This opening permits the exhaust to escape. The remaining pressures give a resultant thrust on the side opposite the opening, and these pressures are what push the rocket along.

Rocket thrust is caused by pressures acting on both the combustion chamber and nozzle

The shape of the nozzle is important. Consider a balloon propelled by air coming out of a tapering nozzle. In such a case the combination of air pressure and viscous friction is such that the nozzle does not push the balloon but is *pulled* by it.[35] Using a convergent/divergent nozzle gives more force since the exhaust also presses on it as it expands outwards, roughly doubling the total force. If propellant gas is continuously added to the chamber then these pressures can be maintained for as long as propellant remains. Note that in the case of liquid propellant engines, the pumps moving the propellant into the combustion chamber must maintain a pressure larger than the combustion chamber -typically on the order of 100 atmospheres.[2]

As a side effect, these pressures on the rocket also act on the exhaust in the opposite direction and accelerate this exhaust to very high speeds (according to Newton's Third Law).[2] From the principle of conservation of momentum the speed of the exhaust of a rocket determines how much momentum increase is created for a given amount of propellant. This is called the rocket's *specific impulse*.[2] Because a rocket, propellant and exhaust in flight, without any external perturbations, may be considered as a closed system, the total momentum is always constant. Therefore, the faster the net speed of the exhaust in one direction, the greater the speed of the rocket can achieve in the opposite direction. This is especially true since the rocket body's mass is typically far lower than the final total exhaust mass.

Forces on a rocket in flight

The general study of the forces on a rocket is part of the field of ballistics. Spacecraft are further studied in the subfield of astrodynamics.

Forces on a rocket in flight

Flying rockets are primarily affected by the following:[36]

- Thrust from the engine(s)
- Gravity from celestial bodies
- Drag if moving in atmosphere
- Lift; usually relatively small effect except for rocket-powered aircraft

Rockets that must travel through the air are usually tall and thin as this shape gives a high ballistic coefficient and minimizes drag losses.

In addition, the inertia and centrifugal pseudo-force can be significant due to the path of the rocket around the center of a celestial body; when high enough speeds in the right direction and altitude are achieved a stable orbit or escape velocity is obtained.

These forces, with a stabilizing tail (the *empennage*) present will, unless deliberate control efforts are made, naturally cause the vehicle to follow a roughly parabolic trajectory termed a gravity turn, and this trajectory is often used at least during the initial part of a launch. (This is true even if the rocket engine is mounted at the nose.) Vehicles can thus maintain low or even zero angle of attack, which minimizes transverse stress on the launch vehicle, permitting a weaker, and hence lighter, launch vehicle.[37][38]

Drag

Drag is a force opposite to the direction of the rocket's motion. This decreases acceleration of the vehicle and produces structural loads. Deceleration force for fast-moving rockets are calculated using the drag equation.

Drag can be minimised by an aerodynamic nose cone and by using a shape with a high ballistic coefficient (the "classic" rocket shape—long and thin), and by keeping the rocket's angle of attack as low as possible.

During a rocket launch, as the vehicle speed increases, and the atmosphere thins, there is a point of maximum aerodynamic drag called Max Q. This determines the minimum aerodynamic strength of the vehicle, as the rocket must avoid buckling under these forces.[39]

Net thrust

A typical rocket engine can handle a significant fraction of its own mass in propellant each second, with the propellant leaving the nozzle at several kilometres per second. This means that the thrust-to-weight ratio of a rocket engine, and often the entire vehicle can be very high, in extreme cases over 100. This compares with other jet propulsion engines that can exceed 5 for some of the better[40] engines.[41]

It can be shown that the net thrust of a rocket is:

$$F_n = \dot{m}\, v_e$$ [2]:2–14

where:

$\dot{m} =$ propellant flow (kg/s or lb/s)

$v_e =$ the effective exhaust velocity (m/s or ft/s)

The effective exhaust velocity v_e is more or less the speed the exhaust leaves the vehicle, and in the vacuum of space, the effective exhaust velocity is often equal to the actual average exhaust speed along the thrust axis. However, the effective exhaust velocity allows for various losses, and notably, is reduced when operated within an atmosphere.

A rocket jet shape varies based on external air pressure. From top to bottom: Underexpanded Ideally Expanded Overexpanded Grossly overexpanded

The rate of propellant flow through a rocket engine is often deliberately varied over a flight, to provide a way to control the thrust and thus the airspeed of the vehicle. This, for example, allows minimization of aerodynamic losses[39] and can limit the increase of *g*-forces due to the reduction in propellant load.

Total impulse

Impulse is defined as a force acting on an object over time, which in the absence of opposing forces (gravity and aerodynamic drag), changes the momentum (integral of mass and velocity) of the object. As such, it is the best performance class (payload mass and terminal velocity capability) indicator of a rocket, rather than takeoff thrust, mass, or "power". The total impulse of a rocket (stage) burning its propellant is:[2]:27

$$I = \int F dt$$

When there is fixed thrust, this is simply:

$$I = Ft$$

The total impulse of a multi-stage rocket is the sum of the impulses of the individual stages.

Specific impulse

As can be seen from the thrust equation, the effective speed of the exhaust controls the amount of thrust produced from a particular quantity of fuel burnt per second.

An equivalent measure, the net impulse per weight unit of propellant expelled, is called specific Impulse, I_{sp}, and this is one of the most important figures that describes a rocket's performance. It is defined such that it is related to the effective exhaust velocity by:

$$v_e = I_{sp} \cdot g_0$$ [2]:29

where:

I_{sp} has units of seconds
g_0 is the acceleration at the surface of the Earth

I_{sp} in vacuum of various rockets

Rocket	Propellants	I_{sp}, vacuum (s)
Space shuttle liquid engines	LOX/LH_2	453[42]
Space shuttle solid motors	APCP	268[42]
Space shuttle OMS	NTO/MMH	313[42]
Saturn V stage 1	LOX/RP-1	304[42]

Thus, the greater the specific impulse, the greater the net thrust and performance of the engine. I_{sp} is determined by measurement while testing the engine. In practice the effective exhaust velocities of rockets varies but can be extremely high, ~4500 m/s, about 15 times the sea level speed of sound in air.

Delta-v (rocket equation)

The delta-v capacity of a rocket is the theoretical total change in velocity that a rocket can achieve without any external interference (without air drag or gravity or other forces).

A map of approximate Delta-v's around the solar system between Earth and Mars[43][44]

When v_e is constant, the delta-v that a rocket vehicle can provide can be calculated from the Tsiolkovsky rocket equation:[45]

$$\Delta v = v_e \ln \frac{m_0}{m_1}$$

where:

- m_0 is the initial total mass, including propellant, in kg (or lb)
- m_1 is the final total mass in kg (or lb)
- v_e is the effective exhaust velocity in m/s (or ft/s)
- Δv is the delta-v in m/s (or ft/s)

When launched from the Earth practical delta-v's for a single rockets carrying payloads can be a few km/s. Some theoretical designs have rockets with delta-v's over 9 km/s.

The required delta-v can also be calculated for a particular manoeuvre; for example the delta-v to launch from the surface of the Earth to Low earth orbit is about 9.7 km/s, which leaves the vehicle with a sideways speed of about 7.8 km/s at an altitude of around 200 km. In this manoeuvre about 1.9 km/s is lost in air drag, gravity drag and gaining altitude.

The ratio $\frac{m_0}{m_1}$ is sometimes called the *mass ratio*.

Mass ratios

Almost all of a launch vehicle's mass consists of propellant.[46] Mass ratio is, for any 'burn', the ratio between the rocket's initial mass and its final mass.[47] Everything else being equal, a high mass ratio is desirable for good performance, since it indicates that the rocket is lightweight and hence performs better, for essentially the same reasons that low weight is desirable in sports cars.

Rockets as a group have the highest thrust-to-weight ratio of any type of engine; and this helps vehicles achieve high mass ratios, which improves the performance of flights. The higher the ratio, the less engine mass is needed to be carried. This permits the carrying of even more propellant, enormously improving the delta-v. Alternatively, some rockets such as for rescue scenarios or racing carry relatively little propellant and payload and thus need only a lightweight structure and instead achieve high accelerations. For example, the Soyuz escape system can produce 20g.[21]

Achievable mass ratios are highly dependent on many factors such as propellant type, the design of engine the

vehicle uses, structural safety margins and construction techniques.

The highest mass ratios are generally achieved with liquid rockets, and these types are usually used for orbital launch vehicles, a situation which calls for a high delta-v. Liquid propellants generally have densities similar to water (with the notable exceptions of liquid hydrogen and liquid methane), and these types are able to use lightweight, low pressure tanks and typically run high-performance turbopumps to force the propellant into the combustion chamber.

Some notable mass fractions are found in the following table (some aircraft are included for comparison purposes):

Vehicle	Takeoff Mass	Final Mass	Mass ratio	Mass fraction
Ariane 5 (vehicle + payload)	746,000 kg [48] (~1,645,000 lb)	2,700 kg + 16,000 kg[48] (~6,000 lb + ~35,300 lb)	39.9	0.975
Titan 23G first stage	117,020 kg (258,000 lb)	4,760 kg (10,500 lb)	24.6	0.959
Saturn V	3,038,500 kg[49] (~6,700,000 lb)	13,300 kg + 118,000 kg[49] (~29,320 lb + ~260,150 lb)	23.1	0.957
Space Shuttle (vehicle + payload)	2,040,000 kg (~4,500,000 lb)	104,000 kg + 28,800 kg (~230,000 lb + ~63,500 lb)	15.4	0.935
Saturn 1B (stage only)	448,648 kg[50] (989,100 lb)	41,594 kg[50] (91,700 lb)	10.7	0.907
Virgin Atlantic GlobalFlyer	10,024.39 kg (22,100 lb)	1,678.3 kg (3,700 lb)	6.0	0.83
V-2	13,000 kg (~28,660 lb) (12.8 ton)		3.85	0.74 [51]
X-15	15,420 kg (34,000 lb)	6,620 kg (14,600 lb)	2.3	0.57[52]
Concorde	~181,000 kg (400,000 lb [52])		2	0.5[52]
Boeing 747	~363,000 kg (800,000 lb[52])		2	0.5[52]

The Tsiolkovsky rocket equation gives a relationship between the mass ratio and the final velocity in multiples of the exhaust speed

Staging

Thus far, the required velocity (delta-v) to achieve orbit has been unattainable by any single rocket because the propellant, tankage, structure, guidance, valves and engines and so on, take a particular minimum percentage of take-off mass that is too great for the propellant it carries to achieve that delta-v. Since Single-stage-to-orbit has so far not been achievable, orbital rockets always have more than one stage.

Spacecraft staging involves dropping off unnecessary parts of the rocket to reduce mass.

For example, the first stage of the Saturn V, carrying the weight of the upper stages, was able to achieve a mass ratio of about 10, and achieved a specific impulse of 263 seconds. This gives a delta-v of around 5.9 km/s whereas around 9.4 km/s delta-v is needed to achieve orbit with all losses allowed for.

This problem is frequently solved by staging — the rocket sheds excess weight (usually empty tankage and associated engines) during launch. Staging is either *serial* where the rockets light after the previous stage has fallen away, or *parallel*, where rockets are burning together and then detach when they burn out.[53]

Apollo 6 while dropping the interstage ring

The maximum speeds that can be achieved with staging is theoretically limited only by the speed of light. However the payload that can be carried goes down geometrically with each extra stage needed, while the additional delta-v for each stage is simply additive.

Acceleration and thrust-to-weight ratio

From Newton's second law, the acceleration, a, of a vehicle is simply:

$$a = \frac{F_n}{m}$$

Where m is the instantaneous mass of the vehicle and F_n is the net force acting on the rocket (mostly thrust but air drag and other forces can play a part.)

As the remaining propellant decreases, rocket vehicles become lighter and their acceleration tends to increase until the propellant is exhausted. This means that much of the speed change occurs towards the end of the burn when the vehicle is much lighter.[2] However, the thrust can be throttled to offset or vary this if needed. Discontinuities in acceleration also occur when stages burn out, often starting at a lower acceleration with each new stage firing.

Peak accelerations can be increased by designing the vehicle with a reduced mass, usually achieved by a reduction in the fuel load and tankage and associated structures, but obviously this reduces range, delta-v and burn time. Still, for some applications that rockets are used for, a high peak acceleration applied for just a short time is highly desirable.

The minimal mass of vehicle consists of a rocket engine with minimal fuel and structure to carry it. In that case the thrust-to-weight ratio[nb 3] of the rocket engine limits the maximum acceleration that can be designed. It turns out that rocket engines generally have truly excellent thrust to weight ratios (137 for the NK-33

engine,[54] some solid rockets are over 1000[2]:442), and nearly all really high-g vehicles employ or have employed rockets.

The high accelerations that rockets naturally possess means that rocket vehicles are often capable of vertical takeoff, and in some cases, with suitable guidance and control of the engines, also vertical landing. For these operations to be done it is necessary for a vehicle's engines to provide more than the local gravitational acceleration.

Energy

Energy efficiency

Rocket launch vehicles take-off with a great deal of flames, noise and drama, and it might seem obvious that they are grievously inefficient. However, while they are far from perfect, their energy efficiency is not as bad as might be supposed.

Space Shuttle *Atlantis* during launch phase

The energy density of a typical rocket propellant is often around one-third that of conventional hydrocarbon fuels; the bulk of the mass is (often relatively inexpensive) oxidizer. Nevertheless, at take-off the rocket has a great deal of energy in the fuel and oxidizer stored within the vehicle. It is of course desirable that as much of the energy of the propellant end up as kinetic or potential energy of the body of the rocket as possible.

Energy from the fuel is lost in air drag and gravity drag and is used for the rocket to gain altitude and speed. However, much of the lost energy ends up in the exhaust.[2]:37–38

In a chemical propulsion device, the engine efficiency is simply the ratio of the kinetic power of the exhaust gases and the power available from the chemical reaction:[2]:37–38

$$\eta_c = \frac{\frac{1}{2}\dot{m}v_e^2}{\eta_{combustion} P_{chem}}$$

100% efficiency within the engine (engine efficiency $\eta_c = 100\%$) would mean that all the heat energy of the combustion products is converted into kinetic energy of the jet. This is not possible, but the near-adiabatic high expansion ratio nozzles that can be used with rockets come surprisingly close: when the nozzle expands the gas, the gas is cooled and accelerated, and an energy efficiency of up to 70% can be achieved. Most of the rest is heat energy in the exhaust that is not recovered.[2]:37–38 The high efficiency is a consequence of the fact that rocket combustion can be performed at very high temperatures and the gas is finally released at much lower temperatures, and so giving good Carnot efficiency.

However, engine efficiency is not the whole story. In common with the other jet-based engines, but particularly in rockets due to their high and typically fixed exhaust speeds, rocket vehicles are extremely inefficient at low speeds irrespective of the engine efficiency. The problem is that at low speeds, the exhaust carries away a huge amount of kinetic energy rearward. This phenomenon is termed propulsive efficiency (η_p).[2]:37–38

However, as speeds rise, the resultant exhaust speed goes down, and the overall vehicle energetic efficiency rises, reaching a peak of around 100% of the engine efficiency when the vehicle is travelling exactly at the

same speed that the exhaust is emitted. In this case the exhaust would ideally stop dead in space behind the moving vehicle, taking away zero energy, and from conservation of energy, all the energy would end up in the vehicle. The efficiency then drops off again at even higher speeds as the exhaust ends up travelling forwards-trailing behind the vehicle.

From these principles it can be shown that the propulsive efficiency η_p for a rocket moving at speed u with an exhaust velocity c is:

$$\eta_p = \frac{2\frac{u}{c}}{1+(\frac{u}{c})^2}$$ [2]:37–38

And the overall (instantaneous) energy efficiency η is:

$$\eta = \eta_p \eta_c$$

Plot of instantaneous propulsive efficiency (blue) and overall efficiency for a rocket accelerating from rest (red) as percentages of the engine efficiency

For example, from the equation, with an η_c of 0.7, a rocket flying at Mach 0.85 (which most aircraft cruise at) with an exhaust velocity of Mach 10, would have a predicted overall energy efficiency of 5.9%, whereas a conventional, modern, air-breathing jet engine achieves closer to 35% efficiency. Thus a rocket would need about 6x more energy; and allowing for the specific energy of rocket propellant being around one third that of conventional air fuel, roughly 18x more mass of propellant would need to be carried for the same journey. This is why rockets are rarely if ever used for general aviation.

Since the energy ultimately comes from fuel, these considerations mean that rockets are mainly useful when a very high speed is required, such as ICBMs or orbital launch. For example, NASA's space shuttle fires its engines for around 8.5 minutes, consuming 1,000 tonnes of solid propellant (containing 16% aluminium) and an additional 2,000,000 litres of liquid propellant (106,261 kg of liquid hydrogen fuel) to lift the 100,000 kg vehicle (including the 25,000 kg payload) to an altitude of 111 km and an orbital velocity of 30,000 km/h. At this altitude and velocity, the vehicle has a kinetic energy of about 3 TJ and a potential energy of roughly 200 GJ. Given the initial energy of 20 TJ,[nb 4] the Space Shuttle is about 16% energy efficient at launching the orbiter.

Thus jet engines, with a better match between speed and jet exhaust speed (such as turbofans—in spite of their worse η_c)—dominate for subsonic and supersonic atmospheric use, while rockets work best at hypersonic speeds. On the other hand, rockets serve in many short-range *relatively* low speed military applications where their low-speed inefficiency is outweighed by their extremely high thrust and hence high accelerations.

Oberth effect

One subtle feature of rockets relates to energy. A rocket stage, while carrying a given load, is capable of giving a particular delta-v. This delta-v means that the speed increases (or decreases) by a particular amount, independent of the initial speed. However, because kinetic energy is a square law on speed, this means that the faster the rocket is travelling before the burn the more orbital energy it gains or loses.

This fact is used in interplanetary travel. It means that the amount of delta-v to reach other planets, over and above that to reach escape velocity can be much less if the delta-v is applied when the rocket is travelling at high speeds, close to the Earth or other planetary surface; whereas waiting until the rocket has slowed at altitude multiplies up the effort required to achieve the desired trajectory.

Safety, reliability and accidents

The reliability of rockets, as for all physical systems, is dependent on the quality of engineering design and construction.

Space Shuttle Challenger was torn apart T+73 seconds after hot gases escaped the SRBs, causing the breakup of the Shuttle stack

Because of the enormous chemical energy in rocket propellants (greater energy by weight than explosives, but lower than gasoline), consequences of accidents can be severe. Most space missions have some problems.[55] In 1986, following the Space Shuttle Challenger disaster, American physicist Richard Feynman, having served on the Rogers Commission estimated that the chance of an unsafe condition for a launch of the Shuttle was very roughly 1%;[56] more recently the historical per person-flight risk in orbital spaceflight has been calculated to be around 2%[57] or 4%.[58]

Costs and economics

The costs of rockets can be roughly divided into propellant costs, the costs of obtaining and/or producing the 'dry mass' of the rocket, and the costs of any required support equipment and facilities.[59]

Most of the takeoff mass of a rocket is normally propellant. However propellant is seldom more than a few times more expensive than gasoline per kilogram (as of 2009 gasoline was about $1/kg [$0.45/lb] or less), and although substantial amounts are needed, for all but the very cheapest rockets, it turns out that the propellant costs are usually comparatively small, although not completely negligible.[59] With liquid oxygen costing $0.15 per kilogram ($0.068/lb) and liquid hydrogen $2.20/kg ($1.00/lb), the Space Shuttle in 2009 had a liquid propellant expense of approximately $1.4 million for each launch that cost $450 million from other expenses (with 40% of the mass of propellants used by it being liquids in the external fuel tank, 60% solids in the SRBs).[60][61][62]

Even though a rocket's non-propellant, dry mass is often only between 5-20% of total mass,[63] nevertheless this cost dominates. For hardware with the performance used in orbital launch vehicles, expenses of $2000–$10,000+ per kilogram of dry weight are common, primarily from engineering, fabrication, and testing; raw materials amount to typically around 2% of total expense.[64][65] For most rockets except reusable ones (shuttle engines) the engines need not function more than a few minutes, which simplifies design.

Extreme performance requirements for rockets reaching orbit correlate with high cost, including intensive quality control to ensure reliability despite the limited safety factors allowable for weight reasons.[65] Components produced in small numbers if not individually machined can prevent amortization of R&D and facility costs over mass production to the degree seen in more pedestrian manufacturing.[65] Amongst liquid-fueled rockets, complexity can be influenced by how much hardware must be lightweight, like pressure-fed engines can have two orders of magnitude lesser part count than pump-fed engines but lead to more weight by needing greater tank pressure, most often used in just small maneuvering thrusters as a consequence.[65]

To change the preceding factors for orbital launch vehicles, proposed methods have included mass-producing simple rockets in large quantities or on large scale,[59] or developing reusable rockets meant to fly very frequently to amortize their up-front expense over many payloads, or reducing rocket performance requirements by constructing a hypothetical non-rocket spacelaunch system for part of the velocity to orbit (or

all of it but with most methods involving some rocket use).

The costs of support equipment, range costs and launch pads generally scale up with the size of the rocket, but vary less with launch rate, and so may be considered to be approximately a fixed cost.[59]

Rockets in applications other than launch to orbit (such as military rockets and rocket-assisted take off), commonly not needing comparable performance and sometimes mass-produced, are often relatively inexpensive.

- Rocket mail—the delivery of mail by rocket or missile.

Notes

1. English *rocket*, first attested in 1566 (OED), adopted from the Italian term, given due to the similarity in shape to the bobbin or spool used to hold the thread to be fed to a spinning wheel. The modern Italian term is *razzo*.
2. The confusion is illustrated in http://science.howstuffworks.com/rocket.htm; “If you have ever seen a big fire hose spraying water, you may have noticed that it takes a lot of strength to hold the hose (sometimes you will see two or three firefighters holding the hose). The hose is acting like a rocket engine. The hose is throwing water in one direction, and the firefighters are using their strength and weight to counteract the reaction. If they were to let go of the hose, it would thrash around with tremendous force. If the firefighters were all standing on skateboards, the hose would propel them backward at great speed!”
3. “thrust-to-weight ratio F/W_g is a dimensionless parameter that is identical to the acceleration of the rocket propulsion system (expressed in multiples of g_0) ... in a gravity-free vacuum”[2]:442
4. The energy density is 31MJ per kg for aluminum and 143 MJ/kg for liquid hydrogen, this means that the vehicle consumes around 5 TJ of solid propellant and 15 TJ of hydrogen fuel.

Rodale Press's Research and Development folks have devised a homestead-scale thresher, which has been used at the New Organic Gardening Experimental Farm to thresh crops ranging from

Rodale Thresher

soybeans to amaranth. The machine is not fully refined, so a certain amount of hand-winnowing may be necessary. But it is an inexpensive alternative to the sophisticated and expensive seed threshers and cleaners on the market. It will separate most any cereal crop into seed and straw and can be operated by only one or two people. Different pulley sizes let you alter the threshing speed as best suits each crop.

Materials:

2–4′ × 8′ sheets of ¾″ exterior plywood	or	2 sides (see diagram) 1 pc. 12″ × 18″ 1 pc. 12″ × 34″ 1 pc. 12″ × 21″ 1 pc. 11¾″ × 5″
1′ length of 6″ steel pipe		
3/16″ steel plates		2 pc. 5 × 2½″ 1 pc. 10″ × 13″
4 pillar blocks for ¾″ shaft		
14½′ length of #130 5/16″ steel coil chain		26 sets, 3 links each, 6½″ long
2–1½′ steel shafts		
misc. #10 wood screws		
5/16″ or ⅜″ hex bolts and nuts		
1½ horsepower motor with step sheaves		

2–4″ pulleys
1–6″ pulley
1–8″ pulley

Construction: Cut all the plywood parts for the thresher body as indicated on the materials list. The sides are formed as shown, and each must have a 7½-inch-wide cutout for the motor and two 1¾-inch holes for the flail shafts. Fasten the parts together with 2-inch #10 screws.

To make the flail shafts, cut the 14½ feet of chain into 26 three-link sets. Weld the cuts shut and mount the middle chain link on the steel bars. Arrange the three-link sets so they fit snugly together at 90° angles to the link next to them. Now weld them to the shaft. Once 13 links have been fixed to each steel shaft, then secure the shafts in place with pillar blocks, bolting them to the side of the thresher.

The next job can be done with a hacksaw but if you have access to an oxyacetylene torch, use it. Divide the 1-foot-long

CUT
STEEL PIPE

MOTOR MOUNT BOLTS
MOTOR HOLE
10"
13"
3/8" ADJUSTMENT GROOVES

CONCAVE
STEEL PIPE
WELD
3/8"
5"

6-inch steel pipe into quarters lengthwise. Then cut supporting plates from scrap steel with grooves for a sliding adjustment, as shown. Weld the steel supports to each pipe section and mount them below the cylinders so that the spinning chain links just miss the pipe basin.

The motor mounting plate will have to be adapted to your particular motor but you can use this illustration as a guide.

You may select pulley (sheave) sizes to fit your purpose. To make ours adaptable, we used a four-inch step sheave on the motor, a six-inch step sheave on one cylinder end and an eight-inch sheave on the other cylinder end. On the side opposite the motor, install two identical pulleys of any size; we used four-inch ones. Run a V-belt around them so that the shafts turn in unison.

Attach the motor to the mounting plate with four bolts. Hoist the motor into a good central position so that any change you may want to make is only a vertical one. Now bolt the mounting plate to the side of the thresher and adjust the height according to the V-belt fitting.

Operation: You'll need a screen of appropriate size for each different grain you want to thresh. Make a frame one foot wide and anywhere from three feet to five feet long to fit in right below the second concave. Beaten grain and straw will fly from the cylinders onto the screen. The smaller, heavier grain will fall, while the straw is blown on through. You may find it a help to brush the straw against the screen to help separate the seed. Two people are better than one for this job.

We found that the thresher worked better at a slow speed for larger items, like soybeans, and at fast speeds for the small items. You can be your own judge here.

Caution! Be sure to keep your hands away from the grinding chamber. If you are allergic to dust, you may want to enclose the threshing chamber better.

Rohn Emergency Scale

From Wikipedia, the free encyclopedia

The **Rohn Emergency Scale**[1] is a scale on which the magnitude (intensity)[2] of an emergency is measured. It was first proposed in 2006, and explained in more detail in a peer-reviewed paper presented at a 2007 system sciences conference.[3] The idea was further refined later that year.[4] The need for such a scale was ratified in two later independent publications.[5][6] It is the first scale that quantifies any emergency based on a mathematical model. The scale can be tailored for use at any geographic level – city, county, state or continent. It can be used to monitor the development of an ongoing emergency event, as well as forecast the probability and nature of a potential developing emergency and in the planning and execution of a National Response Plan.

Existing emergency-related scales

Scales relating to natural phenomena that may result in an emergency are numerous. This section provides a review of several notable emergency related scales. They concentrate mainly on weather and environmental scales that provide a common understanding and lexicon with which to understand the level of intensity and impact of a crisis. Some scales are used before and/or during a crisis to predict the potential intensity and impact of an event and provide an understanding that is useful for preventative and recovery measures. Other scales are used for post-event classification. Most of these scales are descriptive rather than quantitative, which makes them subjective and ambiguous.

1805 Beaufort scale[7]
1931 Modified Mercalli intensity scale[8]
1935 Richter magnitude scale[9] (superseded by the Moment magnitude scale)
1969 Saffir–Simpson hurricane wind scale[10]
1971 Fujita scale[11] (superseded by Enhanced Fujita scale in 2007[12])
1982 Volcanic explosivity index
1990 International Nuclear Event Scale[13]
1999 Air quality index[14]

Variables common to all emergencies

According to the Rohn Emergency Scale, all emergencies can be described by three independent dimensions: (a) scope; (b) topographical change (or lack thereof); and (c) speed of change. The intersection of the three dimensions provides a detailed scale for defining any emergency,[1] as depicted on the Emergency Scale Website.[15]

Scope

The scope of an emergency in the Rohn scale is represented as a continuous variable with a lower limit of zero and a theoretical calculable upper limit. The Rohn Emergency Scale use two parameters that form the scope: percent of affected humans out of the entire population, and damages, or loss, as a percentile of a given Gross National Product (GNP). Where applied to a specific locality, this parameter may be represented by a Gross State Product, Gross Regional Product, or any similar measure of economic activity appropriate to the entity under emergency.

Topography

A topographical change means a measurable and noticeable change in land characteristics, in terms of elevation, slope, orientation, and land coverage. These could be either natural (e.g., trees) or artificial (e.g., houses). Non-topographical emergencies are situations where the emergency is non-physical in nature. The collapse of the New York stock market in 1929 is such an example, and the global liquidity crisis of August 2007[16] is another example. The model treats topographical change as a continuum ranging between 0 and 1 that gives the estimated visual fractional change in the environment.

Speed of change

An emergency is typified by a departure from normal state of affairs. The scale uses the change of the number of victims over time and economical losses over time to calculate a rate of change that is of utmost importance to society (e.g., life and a proxy for quality of life).

Emergency scale mathematical model

The scale is a normalized function whose variables are scope (*S*), topography (*T*), and rate of change (*D*), expressed as

$$E = Emergency = f(S, T, D).$$

These parameters are defined as follows:

Scope

$$\text{Scope} = \frac{\text{RawScope}}{\text{MaxScope}}$$

where

$$\text{RawScope} = \left(\frac{\text{Victims}}{\text{Population}} + \frac{\text{Monetary Losses}}{\text{GNP}}\right)^{W}$$

where

$$W = \left(\frac{\ln(\text{Victims})}{\ln(\text{Monetary Losses})}\right)^{\beta}$$

β is a coefficient which the model creator calculated to be 1.26 ± 0.03,
and

$$\text{MaxScope} = \left(\frac{0.7*\text{Population}}{\text{Population}} + \frac{0.5*\text{GNP}}{\text{GNP}}\right)^V,$$

where

$$V = \frac{\ln(\text{Victims})}{\ln(\text{Monetary Losses})}$$

The model loosely assumes that a society whose majority of the population (70% in this model) is affected and half of its GNP is drained as a result of a calamity reaches a breaking point of disintegration. Sociologists and economists may come up with a better estimate.

Topographical change

$$\frac{\text{Volume before the event}}{\text{Volume after the event}}$$ or zero for non-topographical events.

Rate of change

$$\frac{d(\text{Victims})}{d(\text{Time})} \text{ and } \frac{d(\text{Losses})}{d(\text{Time})}$$

comprise the rate of change that is of utmost importance to society and therefore incorporated in the model.

Simplified scale for public communications

In some instances, it may be preferable to have an integral scale to more simply and dramatically convey the extent of an emergency, with a range, say, from 1 to 10, and 10 representing the direst emergency. This can be obtained from the function above in any number of ways. One of them is the ceiling function. Another one is a single number representing the volume under the 3D emergency scale.

Roller-compacted concrete

From Wikipedia, the free encyclopedia

Roller-compacted concrete (**RCC**) or **rolled concrete** is a special blend of concrete that has essentially the same ingredients as conventional concrete but in different ratios, and increasingly with partial substitution of fly ash for Portland cement.[2] RCC is a mix of cement/fly ash, water, sand, aggregate and common additives, but contains much less water. The produced mix is drier and essentially has no slump. RCC is placed in a manner similar to paving; the material is delivered by dump trucks or conveyors, spread by small bulldozers or specially modified asphalt pavers, and then compacted by vibratory rollers.

The rebuilt upper reservoir of the Taum Sauk plant, nearing completion in this photo, is the largest RCC dam in North America.[1]

In dam construction, roller-compacted concrete began its initial development with the construction of the Alpe Gera Dam near Sondrio in North Italy between 1961 and 1964. Concrete was laid in a similar form and method but not rolled.[3][4][5] RCC had been touted in engineering journals during the 1970s as a revolutionary material suitable for, among other things, dam construction.[6] Initially and generally, RCC was used for backfill, sub-base and concrete pavement construction, but increasingly it has been used to build concrete gravity dams because the low cement content and use of fly ash cause less heat to be generated while curing than do conventional mass concrete placements. Roller-compacted concrete has many time and cost benefits over conventional mass concrete dams; these include higher rates of concrete placement, lower material costs and lower costs associated with post-cooling and formwork.

Dam applications

For dam applications, RCC sections are built lift-by-lift in successive horizontal layers resulting in a downstream slope that resembles a concrete staircase. Once a layer is placed, it can immediately support the earth-moving equipment to place the next layer. After RCC is deposited on the lift surface, small dozers typically spread it in one-foot-thick (300mm) layers.[7]

Willow Creek Dam, RCC gravity dam, Oregon, USA

The first RCC dam built in the USA was the Willow Creek Dam on Willow Creek, a tributary in Oregon of the Columbia River. It was constructed by the Army Corps of Engineers between November 1981[8] and February 1983.[6] Construction proceeded well, within a fast schedule and under budget (estimated $50 million, actual $35 million). On initial filling though, it was found that the leakage between the compacted layers within the dam body was unusually high. This condition was treated by traditional remedial grouting at a further cost of $2 million, which initially reduced the leakage by nearly 75%; over the years, seepage has since decreased to less than 10% of its initial flow. Concern over the dam's long-term safety has continued however, although only indirectly related to its RCC construction. Within a few years of construction, problems were noted with stratification of the reservoir water, caused by upstream pollution and anoxic decomposition, which produced hydrogen sulfide gas. Concerns were expressed that this could in turn give rise to sulfuric acid, and thus accelerate damage to the concrete. The controversy itself, as well as its handling, continued for some years. In 2004 an aeration plant was installed to address the root cause in the reservoir, as had been suggested 18 years earlier.[6]

In the quarter century since Willow Creek, considerable research and experimentation have yielded innumerable improvements in concrete mix designs, dam designs and construction methods for roller-compacted concrete dams; by 2008, about 350 RCC dams existed world-wide.[9] Currently the highest dam of this type is the Chinese Longtan Dam, at 216 m, with the Pakistani Diamer-Bhasha Dam under construction at 272 m.

Rolling hitch

From Wikipedia, the free encyclopedia

The **rolling hitch** is a knot (see also Magnus hitch) used to attach a rope to a rod, pole, or another rope. A simple friction hitch, it is used for lengthwise pull along an object rather than at right angles. The rolling hitch is designed to resist lengthwise movement for only a single direction of pull.[1]

A common usage while sailing is for rigging a stopper to relax the tension on a sheet so that a jammed winch or block can be cleared.

Naming

At the turn of the 19th century the knot now known as the "rolling hitch" was called the "Magnus hitch" or "Magner's hitch", and the name "rolling hitch" referred to two round turns and two half-hitches.[2] In 1841 Richard Henry Dana, Jr. used the present-day names in his work *The Seaman's Friend*, and subsequent authors have continued to use this terminology.[1][3]

Names and reference numbers from ABOK, left to right: "Rolling Hitch (1)" (#1734), "Rolling Hitch (2)" (#1735), "Magnus Hitch" (#1736)

There are two slightly different hitches commonly known by the name of "rolling hitch". *The Ashley Book of Knots* identifies these two variations as "Rolling Hitch(1)" and "Rolling Hitch(2)" and numbers them #1734 and #1735 respectively. Despite the potential for confusion with the older usage, Ashley chose the name "Magnus Hitch" to refer to knot #1736, which is simply #1734 tied with the final hitch made in the opposite direction.[4] Since two distinct variations of the rolling hitch are widely referred to by the same name, and Magnus hitch now may refer to a different knot than it used to, the use of Ashley reference numbers for these related hitches can eliminate ambiguity when required. These hitches are pictured at the right.

When a rolling hitch or Magnus hitch is tied around the standing part of the rope to form an adjustable loop, it is often referred to as a taut-line hitch or one of several other names, although some sources fail to differentiate by using a separate name.

Tying

Rolling Hitch(1) #1734

This version is preferred when **attaching a rope to pole or rod.**[4][5] It is effectively a clove hitch with an extra initial turn.

1. Start with a turn around the object. Bring the working end towards the direction of pull and between the standing part and the object.
2. Make another wrap around the object, completing a round turn. The wraps of the round turn should progress towards the desired direction of pull. Bring the working end out over the standing part away from the direction of pull.
3. Complete with a half hitch, moving around the object in the same direction as the first turns, as for a clove hitch.
4. Dress by snugging the hitch around the object before applying load.

Rolling Hitch(2) #1735

This version is preferred when **attaching rope to another rope.**[4][5] The first two turns create an **awning hitch** − a temporary hitch used by riggers when adjusting tent lines.[6] These first two turns are merely a subtle rearrangement in the position of the turns of #1734.

1. Begin by making a turn around the object, bringing the working end back between the object and the standing part. Cross over the standing part away from the desired direction of pull.
2. Make a second turn that exactly follows the first, and hence also passes between the object and standing part and then crosses over the standing part, away from the direction of pull. *Make sure the second turn "tucks" between the first turn and the standing part; that is what gives this version extra grip when made around another rope.*[7]
3. Finish with a half hitch, moving around the object in the same direction as the first turns, as for a clove hitch.
4. Dress by snugging the hitch around the object before applying load.

Magnus Hitch #1736

This is tied exactly as #1734, but with the final hitch in the opposite direction. It can be more tricky to snug-up, since both lines emerge from the same side of the hitch, but it has less tendency to twist under load.

1. Start with a turn around the object. Bring the working end towards the direction of pull and between the standing part and the object.
2. Make another wrap around the object, completing a round turn. The wraps of the round turn should progress towards the desired direction of

pull. Bring the working end out over the standing part away from the direction of pull.
3. Complete with a half hitch, moving around the object in the *opposite* direction as the first turns, as for a cow hitch.
4. Dress by snugging the hitch around the object before applying load.

Security

If the hitch is not made very snug before applying any strain, it will not tighten further under load. When hitching to another rope, Ashley[4] and other sources[7][8] suggest #1735 is more secure. Ashley also states that #1736 has less tendency to twist.[6]

Though effective for moderate loads, the rolling hitch cannot be depended on to hold fast under all conditions. Using stiff and slippery modern fiber ropes, the rolling hitch may be difficult to make hold at all. Friction hitches with additional wraps and more complex structure may provide more security.

The August 2009 edition of *Practical Sailor* magazine tested various knots used for lengthwise tension applications, and came to the conclusion that when using modern synthetic rope the rolling hitch could not be regarded as secure. They recommended the Icicle hitch as a replacement.[9]

Life as an Apprentice in a Suction-Gas Fuelled Power House, at Roma (Queensland, Australia) c. 1950.

J.W. Watson

1. The Vision

Looking back more than half a century, I can see the skinny 13 year old boy who was myself, stopping as usual on his way home from school He is standing astride his Malvern Star bicycle gazing through the big open green doors of the old Roma Power House in Mayne Street, Roma.

He is enthralled as always by the sight of the steadily spinning shiny flywheels taller then himself, he mentally notes which engines are running, watches the open commutators occasionally softly sparking under their rows and columns of carbon brushes, sees the salient pole alternators with their smooth slip-rings. He sees the brass and nickel and glass and shiny black zelamite of the exposed switchboards with their overhead copper bus-bars softly gleaming through the light misty haze. He hears and feels the rhythmic throbbing of the engines and the occasional discordant CLANG as someone inside drops something or steps on an ill-fitting steel chequer plate covering a floor duct. A magical place! He will work there one day!

Photo 1. Roma Power House
(Author's new 1949 Velocette Motorcycle visible)

5. The Machines

In the 1950's, the plant at the Roma Power House (since demolished) at Mayne Street consisted of four suction-gas engines of some 150 to 200 HP each, and three Commonwealth 200 HP wood-burning down-draught suction-gas producer sets, about which there will be more later. I regret now that I have no record of the model or serial numbers of all of the engines, although I do have some crumpled Kodak 6/20 Box Brownie photographs.

Photo 6. No.1 National Engine
The large vertical pipe in the foreground is the gas inlet

Photo 7. No.1 National Engine
Dual ignition system visible
Note a vague picture of Crossley No. 3 rear left

No.1 engine was a vertical four-cylinder National Gas engine Model FA2 (The "2" meaning two valves per cylinder) driving a "Lancashire" 240 volt DC generator at 428 rpm. She had a steel ladder on each side to gain access to the upper level. A quiet, clean and reliable engine, she was subject to violent pre-ignition when she didn't like the quality of the gas she was fed. She had dual ignition; a small open 4-bladed knife switch could select either the Scintilla magneto or the car-type battery/coil ignition system. The drivers somehow learnt that she liked to have the knife switch blades slightly open; the resulting 1/8" gap seemed to intensify the spark at the plugs. She had an external "Streamline" oil filter. Her exhaust note had a distinctive "ringing" tone, especially after her valves were freshly ground. After the town was fully converted to AC, she was re-equipped with an alternator and her speed re-adjusted to 375 rpm, (50 Hertz) but she was never the engine she had been at her design speed of 428.

Photo 8. Two Views of No. 2 Hornsby Engine

No.2 engine was a majestic twin cylinder horizontal open-crank side-shaft Hornsby driving a handsome open 240 volt DC generator at 220 rpm, and was notable for an enormous flywheel between the cylinders. Each cylinder was in fact, practically a separate engine in its own right, sharing only the governor and the mechanical lubricator, thus being called a “Coupled Engine”.

Photo 9. No.2 Engine's DC Generator

She and her "English Electric Dynamo" were beautifully painted dark green with rich gold transfers and ornate lining. She had low-tension trip-magnetos with a moving electrode on the ignitors.

I remember her as a reliable and favourite engine which once ran for 10 months continuously during a period of difficulty with other plant, No.2 was particularly prone to "reversing" if she lost power, more about which will be mentioned later. Her powerful steady "chuff chuff" exhaust note could be heard over a wide area, and those standing nearby could feel the concussion in their chest cavities. Loved by some of us, feared by others, but respected by all. Sadly, she was later to be blown up with dynamite and sold for scrap.

No. 3 engine (of which I have no clear picture) was a Crossley twin cylinder open crank engine driving a 240 volt DC generator, generally similar to No. 2, but on a smaller scale. Considered by the drivers to be a bit of a prima donna, pretty in appearance but with a nervous disposition and demanding attention to get the best out of her. She broke a crankshaft, perhaps due to a generator "reversal", and was out of commission for a long time. She was eventually repaired, but was too small to be of much use. Her DC generator was later removed and mounted alongside the No.5 engine, belt-driven from it in addition to its own shaft-coupled AC alternator. No. 3 was later demolished to make way for a larger engine.

Photo 10. Two Views of No. 4 National Engine

No. 4 engine was a large four cylinder vertical National engine Model 13 x 14, (denoting bore x stroke), driving a 3-phase 240/415 volt AC alternator at 375 rpm. I understood that it was purchased second-hand from a butter factory in Armadale (NSW).

It was a temperamental engine unpopular with the drivers. He (never “she” for some reason) had twin high-tension BTH magnetos and two spark plugs the size of beer bottles per cylinder. A steel ladder gave access to two chequer-plate decks mid-way and at the top of the engine. None shed any tears when he was eventually demolished.

There was some suggestion later that the intake manifold had been incorrectly assembled upside-down when the engine was installed at Roma, resulting in a larger passage for the gas than for the air, but I cannot vouch for this.

Photo 11. No. 4's Alternator

Then there was the "M.A." (motor/alternator), a 240 volt DC motor/generator set of about 100 HP, driving a similarly sized 3-phase 240/415 volt "Weymouth" AC alternator/synchronous motor via a set of ten "A" code vee-belts. The MA set was installed originally to provide the first AC supply in Roma, for the new hospital when it was built in about 1946. With the steady growth of the AC load, the next engine (No. 4) was later installed. The MA could provide either AC or CD as required from the alternate supply, whichever side had spare capacity at the time.

Photo 12. Motor Alternator ("MA") Set

6. Ancillary Plant

There was quite a lot of ancillary plant for the engine cooling systems and producer scrubber water circulation, fuel supply, lubrication oil reclamation, compressed air starting systems and so on. We had our own sub-artesian water bore pumped up by compressed air.

7. The Gas Producers

Three down-draught suction-gas producers, or gas generators, fed the four engines through a common header pipe. Fuel for the producers was sawn "Ironbark" hardwood (*Eucalyptus paniculata drepanphylla)* blocks. To supply the wood fuel, a small sawmill was operated on-site by contractors. The sawn blocks were loaded onto steel skips (wagons) running on 24 inch gauge rail tracks. Each skip was loaded to 15cwt. (3/4 ton or 1,680 lbs.) Each block would have been about 18 inches in diameter and 18 inches long, and each weighed some 80 lb. when dry. There would have been on average about 20 blocks per skip.

The skips were hand pushed to the back of the powerhouse (over a weighbridge) by contractors each weekday and left adjacent to the turntable for the use of the night shift engine drivers. Firing was done by the power house labourer during the day shifts on weekdays, and by the engine driver and/or an apprentice on night shifts and weekends. Apprentices worked with the drivers on day and afternoon shifts six days per week.

8. Producer Gas

In small generating stations where the capital cost of steam turbines is prohibitive, diesel generators are now generally used. Because power houses for small towns are, at the best, marginally profitable, the capital cost and the cost of fuel must be kept low. In those days, much of the transporting of diesel fuel was by means of 44 gallon drums, which added to the handling cost. One solution widely used in Australia in the early to mid twentieth century to avoid the cost of diesel fuel was to install gas-fuelled internal combustion engine generators.

Note: The use of the term "gas" in this article refers to Producer Gas, not to gasoline.

Suitable gases include natural gas or the manufactured gases – these could include town gas (obtained by heating coke), gas produced as a by-product of blast furnaces, water-gas (or blue gas) obtained from the action of steam on hot coke, coal gasification from the action of air and steam on pulverized coal and carburetted gas obtained from cracking or enriching oils.

Another alternative is gas generated by various types of simple gas producer adjacent to the engine. Some of these burnt coal, charcoal, wood or even combustible waste such as sawdust, wood-chips or "begasse", the waste fibre from sugar mills. Hardwood was preferable to the softer pines or fibrous material which burnt too quickly. These gas plants are similar in principle and action to the charcoal burning producers widely fitted to motor cars, trucks and tractors during WW2 in Australia and Europe.

When firewood was readily available in the district, many power houses installed wood-burning suction-gas producers. In later years when the supply of suitable wood diminished or its use became a concern, these plants fell into disuse and were replaced by diesel generators, and more recently by gas turbines fuelled by diesel or natural gas, when this became widely available.

In the Roma power house, wood-fired suction-gas producers were used from its inception in 1916 until the 1960's.

9. Constituents of Producer Gas

Wood fired producer gas typically consists of:

Combustible gas:

CO (Carbon Monoxide)	22.0%
CH_4 (Methane)	2.4%
H_2 (Hydrogen)	8.0%

Inert gas:

CO_2 (Carbon Dioxide)	6.6%
N_2 (Nitrogen)	61%

Plus small amounts of impurities - sulphur, ash, moisture, etc.

(Ref. "Standard Handbook for Mechanical Engineers" Baumeister & Marks 1967)

Photo 13. Gas Producer Shed at Roma

Drawing 10.1 Gas Producer

10. Gas Producer Construction

Referring to Drawing 10.1, each gas producer set consisted of (a) the producer, (b) the dust box and (c) and (d), the scrubbers, all mounted above (straddling) a water "seal" pit. A firing stage was constructed above, where a set of 24 inch gauge tracks ran along the line of producers. A typical producer was a vertical steel cylinder lined with firebrick, about 6 feet in diameter and 15 feet high with a conical top of a further 3 feet high tapering in to an opening of some 30 inches in diameter.

A cast iron cover sat on top fitted with a handwheel and a swivelling bracket allowing the lid to be raised a little and swung aside for charging with firewood. The producer had a grate about 3 feet above ground level.

Just above the grate were four steel doors arranged 90° around the circumference, to allow periodic raking of the grate to clear the ash and clinker, if any. Fine ash normally fell through the grate into the seal pit, but quite a lot hung up on the grate, especially if any clinker were present.

The bottoms of the producer below the grate, the dust-box and the scrubbers, consisted of open skirts projecting down below the water level of the "seal". The seal provided a safety valve in case of a "blow", or internal explosion. Ash fell through the grate into the seal and formed a slurry which had to be shovelled out regularly. This was a daily duty of the power house labourer. When the engines were working hard, the seal water would sometimes rock rhythmically due to the suction pulsations.

11. Producer Operation

Again referring to the Drawing 10.1, atmospheric air entered the producer through a series of radial holes of some 1.5 inches in diameter about half way up, usually fitted with venturi-like “tuyere” tubes or nozzles (pronounced “tweeair”).

The producer was started by lighting it from kindling on the grate and progressively adding larger pieces through the top until filled. The lids and doors were left open until the fire burnt well, often overnight. During this period dense clouds of smoke were produced, to the justifiable annoyance of neighbours downwind, as the power house was in a residential area. Once the doors were closed and the producer on line, there was no smoke or fumes emitted except when being fired (recharged with wood fuel) every two hours or so, as the interior of the producer operated slightly below atmospheric pressure, hence the name “suction gas”.

Simply stated, the contents of an operating producer is in the form of a bed of incandescent burning material sitting on the grate and extending perhaps half way up the producer, and above this right to the top lay the progressively less consumed fuel zones where physical and chemical changes occur, up to fresh wood at the top.

In operation, the engines drew atmospheric air in through the tuyeres. This then passed down through the zones to the firebed where the available oxygen was consumed, leaving “producer gas”, produced by the heat of the partially consumed fuel. There being insufficient atmospheric air (i.e., oxygen) for the complete burning of the fuel, the oxygen-starved environment resulted in unconsumed gas, (mixture of combustible and inert) which passed down through the grate.

The very hot gas then exited the producer horizontally between the grate and the water seal via an open bottomed steel dust-box, which contained baffles. The gas then passed upward through the two scrubbers in turn. These consisted of steel cylinders some 5 feet in diameter and 15 feet high, containing a variety of filtering material, typically blocks of firewood, coke or even rocks and perhaps wood-wool at the tops. Water was sprayed down through the scrubbers to cool and wash the gas. This water then drained into the seals which constantly overflowed to an underground tank from where recirculating pumps returned it to the scrubbers through cooling towers. The “clean” and cool gas now passed to the header pipe, running horizontally the length of the powerhouse, to which each engine has its gas intake pipe fitted. Annually the scrubbers were opened up and the filter material cleaned or renewed. This was a dirty and unpopular job.

There was no provision for the storage of gas – the rate of gas generation was determined by the demand of the engines at the time and it was consumed almost immediately.

12. Firing up

Every two hours, the producers had to be fired up. This operation consisted of the operator pushing by hand a full 15 cwt. loaded skip across the turn-table to the hoist platform at ground level. He then climbed the steep wooden stairs to the firing stage, started (with the face-plate starter) the 5 HP DC electric motor, winched up the skip, pulled it off the hoist onto the top turntable, and pushed the skip along the tracks running along the line of producers. The operator then opened the top of each producer in turn via a rather hot hand-wheel and swung the pivoted heavy cast-iron lid clear of the opening which was not much larger than the diameter of the larger blocks. He soon learnt to stand back and wait a few seconds for the *whoosh* while a mini fireball erupted as a gulp of atmospheric oxygen was sucked into the inferno to combine with some gas and momentarily ignite. He would then throw in half a dozen or so blocks. Heavy work for an apprentice, especially when alone! I don't know why, but we never thought of wearing gloves! (Gloves were rarely worn by manual workers in Australia, even to this day).

He would be careful not to leave the top open for more than a few minutes or the engines would begin to pre-ignite due to the rich gas resulting from an excess of air being drawn through the producer. This usually happened when blocks got stuck, and he was unable to close the lid within a few minutes. Sometimes logs hung up within the producer, and had to be released with a long steel bar. The load would drop with a *whoomp* and a shower of sparks, causing the fire to collapse and resulting in all the engines beginning to pre-ignite and backfire due to a surge of rich gas. He would have to slam the top shut if possible, (it was frequently obstructed by a block of wood which failed to drop cleanly), run down to the engine room and adjust the gas and air levers on each engine, then when they had settled down, back to finish the firing.

Engine drivers tended to be lean and agile with callused hands and permanently singed hair and whiskers!

13. Driving The Engines

The Roma plant at this time consisted of one Hornsby and one Crossley twin cylinder horizontal engine and two National vertical four cylinder engines as described.

The intake manifolds of each engine were divided internally into two sections – air and gas, each controlled by its own master control lever. Governing was attended to by control levers and rod-coupled butterfly or flap valves within each cylinder intake port. The air section of the manifold was larger than the gas section, and each section had its own interconnected but individually adjustable butterfly. Air and gas did not finally mix until they were within the combustion chamber. The intake valves had double seats.

Each engine had its individual peculiarity and its own best setting of the master air and gas control valves, and this had to be learnt by the new drivers mainly by experience. It is difficult to teach this technique - learning this magic mixture setting is the black art of producer-gas engine driving. It differs for each engine, for starting and running, even for fine or rainy days. It differs with differences in ambient temperature and humidity, the weather, the moisture content of the wood, and even, we said, with phases of the moon or the engine's mood!

Pre-ignition was common, usually due to a rich gulp of gas when firing-up or from overload. In those days (the 1950's) most power-houses were grossly overloaded from the post-war growth of housing and industry and the difficulty and delay in obtaining new plant.

Pre-ignition could manifest itself from anything from a dull bumping sound to a series of frightening explosions, and when it could not be cured by judicious adjustment of the master levers, the cause was usually incandescent carbon within the cylinder or valve cage. It is the nature of a suction gas plant that the scrubbers fail to remove a lot of the tar-like material from the gas which caries over into the manifolds, valves and cylinders, leading to deposits of soft carbon.

The remedy – first decide which cylinder was the culprit, then run for your tea-mug, fill it with water, scramble up the engine ladder, disconnect the gas butterfly by removing its clevis-pin then close it, unscrew the brass plug in the air manifold and pour in some water. Usually this quenched the glowing carbon, or perhaps the cooling effect broke it away.

It added much to the drama of the moment and to the amusement of the proceedings (from the spectator's point of view) if you managed to drop the brass plug or the clevis pin, either or both of which loved to fall onto the chequer-plate with an alarming *CLANG* to further disturb your quivering nerves, and to roll away out of sight as you were sprayed with sooty water being spat back at you. The engine of course would drop some of its load onto the others, adding to the excitement.

The fun of driving gas-producer powerhouses lay in the total inter-dependence of all of the engines. When one engine became upset by rich or lean gas, they all joined in the game one after the other or all together, since they all sucked on the same gas header. After a period of steady running the state of brightness of the fires and thus the quantity and quality of gas produced would eventually settle down to satisfy the demand.

Merely starting or stopping an engine had to be planned like a battle. Starting an engine meant a preparation period beforehand of raking the fires to dislodge any compacted ash or clinker from the grates and pricking the numerous tuyeres (inserting a long steel rod and wriggling it energetically to ensure the incoming air had a fair passage) in an effort to brighten up the fires and enrich the gas. Later we installed a fan to help brighten the fires to induce a supply of richer gas before starting a new engine and we fitted a test jet cock which we could light and so judge from its colour the richness of the gas.

When the next engine was started, you could expect a period of lean gas until the status quo was re-established. The amount of gas generated was to a large extent automatically controlled by the demand of the engines, and this took some time to equalize. The same enriching procedure was necessary before the peak load time was expected.

Conversely, when an engine was stopped a period of rich gas could be expected for a while. The problem usually was compounded when a sudden unplanned stoppage occurred, or if a load breaker tripped due to a line fault or during electrical storms, upsetting the steady-state conditions.

In rainy weather, when the wood was wet, the engines seemed to run better. This was certainly more fact than just imagination. As well as the oft discussed benefit claimed to be gained by adding a small quantity of water to the intake air, it is a fact that water or steam injected into the producer itself is an essential part of the design of other types of plant, e.g. the “water-gas” referred to in many texts. However, this was not installed in the producers in Roma, where it was generally the opinion that the wood already contained moisture which would not be present in, say, coal or charcoal, and (rightly or wrongly) that in our case this would give short time calorific advantages against long term corrosion and rust problems in all parts of the system including the engine.

19. Historical Footnote

On October 16th 1900, natural gas was discovered in Roma during the sinking of a water bore (well) on Hospital Hill. After six years of debate and bitter argument, the town was reticulated for gas, but this was abandoned when the gas pressure mysteriously fell fourteen days later. In 1908, a disastrous fire occurred at a nearby bore and burnt for three months before being extinguished.

Although there were many later sporadic natural gas and light oil discoveries in the district, the extent of the gas field was not realised or exploited until 1969 when a 300 mile long pipe line was built to supply Brisbane with Roma gas. At one stage, at least one engine at Roma was fuelled by the light crude oil direct, untreated, from a local well. Additional "gas-cum-oil" engines from the closed Dalby power house were installed in Roma, operating from Roma gas. Gas-cum-oil engines start and run on diesel and can be adjusted to run on up to 90% natural gas. They use at least 10% diesel at all times.

The original power house in Mayne Street became known as the OPH (Old Power House). This was demolished and eventually the site was levelled after the NPH (New Power House) was established on the eastern outskirts of Roma, adjacent to the site of the old original aerodrome. Here new engines and later, a 2.5 MW gas turbine were installed, operating from local natural gas. The NPH which eventually had a capacity of nearly 18 MW operated successfully for many years until it too was demolished some time after it closed at 1.15 am on 8th May, 1986, much to the disquiet of the locals. Roma then obtained its electricity supply from the huge Tarong steam power house which supplied a State grid.

Ironically, to complete the circle, a large gas-turbine stand-by power station was recently built on the now vacant Roma NPH site, fuelled by Roma Natural Gas!

Roman cement

From Wikipedia, the free encyclopedia

Roman cement is a substance developed by James Parker in the 1780s, being patented in 1796.[1][2]

The name is misleading as it is nothing like any material used by the Romans, but was a "natural cement" made by burning septaria – nodules that are found in certain clay deposits, and that contain both clay minerals and calcium carbonate. The burnt nodules were ground to a fine powder. This product, made into a mortar with sand, set in 5–15 minutes.[1][2][3] The success of Roman cement led other manufacturers to develop rival products by burning artificial mixtures of clay and chalk.[1][4][5]

Above the ornate south doorway of Lichfield Cathedral stand seven figures carved in Roman cement.

History

There has been recent resurgence of interest in Natural cements and Roman cements due mainly to the need for repair of façades done in this material in the 19th century. The major confusion involved for many people in this subject is the terminology used. Roman cement was originally the name given, by Parker, to the cement he patented which is a Natural cement (i.e. it is a marl (or limestone containing integral clay) dug out of the ground, burnt and ground to a fine powder).[2][5]

In 1791, Parker was granted a patent "Method of Burning bricks, Tiles, Chalk". His second patent in 1796 "A certain Cement or Terras to be used in Aquatic and other Buildings and Stucco Work",[1] covers Roman cement, the term he used in a 1798 pamphlet advertising his cement. He set up his manufacturing plant on Northfleetcreek, Kent.[2] It was notably patented late on but James Parker is still the subject of all the credit.

Later, in the 1800s various sources of the correct type of marl, known also as Cement Stone, were discovered across Europe and so there were a range of natural cements (with varying properties) in use across Europe.[2][5]

An Austrian standard from 1880, providing a contemporary definition of Roman cements, reads: "Roman cements are products obtained from argillaceous marlstones by burning below the sintering temperature. They do not slake in contact with water and must therefore be ground to a floury fineness."[footnote 1][3]

From around 1807 a number of people looked to make artificial versions of this cement (or more strictly hydraulic lime as it was not burnt at fusion temperatures). Amongst these were James Frost who had about twenty patents from 1811 to 1822 including one for "British Cement" and in 1824 Joseph Aspdin, a British bricklayer from Leeds, with his now famous patent for a method of making a cement he called

"Portland cement".[6] This was done by adding various materials together to make an artificial version of natural cement. The name "Portland cement" is also recorded in a directory published in 1823 being associated with William Lockwood, Dave Stewart, and possibly others.[2][5][7]

There then followed a number of independently discovered or copied versions of this "Portland cement" (also referred to as Proto Portland cement). Proto Portland cement had a different chemical makeup from other natural cements being produced at the same time: It was burnt at a higher temperature than other Natural cements and thus crosses the barrier between traditional Vertical Kiln fired Natural cement and the later Horizontal Kiln fired Artificial cements. This cement is not, however, the same as the modern ordinary Portland cement, which can be defined as artificial cement.[5]

The Alamo Portland and Roman Cement Works, in Brackenridge Park, San Antonio, Texas, United States

James Frost is reported to have erected a manufactory for making of an artificial cement in 1826.[8] In 1843, Aspdin's son William improved their cement, which was initially called "Patent Portland cement," although he had no patent. In 1848, William Aspdin further improved his cement and in 1853, he moved to Germany where he was involved in cement making.[7] William Aspdin made what could be called meso-Portland cement (a mix of Portland cement and hydraulic lime).[5][9]

Artificial cement: Development in the 1860s of rotating horizontal kiln technology brought dramatic changes in properties, arguably resulting in modern cement.[5] Certainly it is difficult to define whether an old render was a natural cement (single source marl) or an artificial one, but there is no doubt as whether the cement was fired in a vertical or horizontal kiln. The names Natural cement or Roman cement then defines a cement coming from a single source rock. Early or Proto Portland cement could be used for early cement that comes from a number of sourced and mixed materials.[5] There is no widely used terminology for these 19th-century cements. There had been, in order to rediscover this technology, two projects carried out by the European Union ROCEM and subsequently ROCARE[10] (an ongoing project). Both these only deal with Natural cement - referred to as Roman cement without reference to the early artificial cements.

Footnotes

1. modified in 1890: "Roman cements are products obtained from argillaceous marlstones by burning below the sintering temperature. They do not slake in contact with water and must therefore be ground to a floury fineness." It specifies the range of setting times which facilitated the choice of a suitable material for a given decorative task: "Roman cements bind fast, medium and slow. By fast binding cements one should understand those which with no addition of sand start to harden within 7 minutes from the moment water is added. Roman cement is considered a slow binding variety if hardening starts later than after 15 minutes."

Romance (love)

From Wikipedia, the free encyclopedia

Romance is the expressive and pleasurable feeling from an emotional attraction towards another person often associated with sexual attraction. It is eros rather than agape, philia, or storge.

In the context of romantic love relationships, romance usually implies an expression of one's strong romantic love, or one's deep and strong emotional desires to connect with another person intimately or romantically. Historically, the term *"romance"* originates with the medieval ideal of chivalry as set out in its *chivalric romance* literature.

Humans have a natural inclination to form bonds with one another through social interactions, be it through verbal communication or nonverbal gestures.

The Stolen Kiss by Jean-Honoré Fragonard (1786)

General definitions

The debate over an exact definition of romantic love may be found in literature as well as in the works of psychologists, philosophers, biochemists and other professionals and specialists. Romantic love is a relative term, but generally accepted as a definition that distinguishes moments and situations within intimate relationships to an individual as contributing to a significant relationship connection.

1. The addition of drama to relationships of close, deep and strong love.
2. Psychologist Charles Lindholm defined love to be "...an intense attraction that involves the idealization of the other, within an erotic context, with expectation of enduring sometime into the future."[1]

Historical definition

Historians believe that the actual English word "romance" developed from a vernacular dialect within the French language meaning "verse narrative"—referring to the style of speech, writing, and artistic talents within elite classes. The word was originally an adverb of the Latin origin "Romanicus," meaning "of the Roman style." The connecting notion is that European medieval vernacular tales were usually about chivalric adventure, not combining the idea of love until late into the seventeenth century.

The word *romance* has also developed with other meanings in other languages such as the early nineteenth century Spanish and Italian definitions of "adventurous" and "passionate", sometimes combining the idea of "love affair" or "idealistic quality."

In primitive societies, tension existed between marriage and the erotic, but this was mostly expressed in taboo regarding the menstrual cycle and birth.[2]

Anthropologists such as Claude Lévi-Strauss show that there were complex forms of courtship in ancient as well as contemporary primitive societies. There may not be evidence, however, that members of such societies formed loving relationships distinct from their established customs in a way that would parallel modern romance.[3]

Bernger von Horheim in the *Codex Manesse* (early 14th century)

Before the 18th century, many marriages were not arranged, but rather developed out of more or less spontaneous relationships. After the 18th century, illicit relationships took on a more independent role. In bourgeois marriage, illicitness may have become more formidable and likely to cause tension. In *Ladies of the Leisure Class*, Rutgers University professor Bonnie G. Smith depicts courtship and marriage rituals that may be viewed as oppressive to modern people. She writes "When the young women of the Nord married, they did so without illusions of love and romance. They acted within a framework of concern for the reproduction of bloodlines according to financial, professional, and sometimes political interests." Subsequent sexual revolution has lessened the conflicts arising out of liberalism, but not eliminated them.

Anthony Giddens, in his book *The Transformation of Intimacy: Sexuality, Love and Eroticism in Modern Society*, states that romantic love introduced the idea of a narrative into an individual's life. He adds that telling a story was one of the meanings of romance. According to Giddens, the rise of romantic love more or less coincided with the emergence of the novel. It was then that romantic love, associated with freedom and therefore the ideals of romantic love, created the ties between freedom and self-realization.

David R. Shumway, in his book *Romance, Intimacy, and The Marriage Crisis*, states that the discourse of intimacy emerged in the last third of the 20th century and that this discourse claimed to be able to explain how marriage and other relationships worked. For the discourse of intimacy emotional closeness was much more important than passion. This does not mean by any means that intimacy is to replace romance. On the contrary, intimacy and romance coexist.[4]

The 21st century has seen the growth of globalization and people now live in a world of transformations that affect almost every aspect of our lives, and love has not been the exception. One example of the changes experienced in relationships was explored by Giddens regarding homosexual relationships. According to Giddens since homosexuals were not able to marry they were forced to pioneer more open and negotiated relationships. This kind of relationships then permeated the heterosexual population.

Shumway also states that together with the growth of capitalism the older social relations dissolved, including marriage. Marriage meaning for women changed as they had more socially acceptable alternatives and were less willing to accept unhappy relations and, therefore, divorce rates substantially increased.

The discourse of romance continues to exist today together with intimacy. Shumway states that on the one hand, romance is the part that offers adventure and intense emotions while offering the possibility to find the perfect mate. On the other hand, intimacy offers deep communication, friendship, and long lasting sharing.

Popularization of love

"La Belle Dame sans Merci" 1893, by John William Waterhouse (1849-1917)

The conception of romantic love was popularized in Western culture by the concept of courtly love. Chevaliers, or knights in the Middle Ages, engaged in what were usually non-physical and non-marital relationships with women of nobility of whom they served. These relations were highly elaborate and ritualized in a complexity that was steeped in a framework of tradition, which stemmed from theories of etiquette derived out of chivalry as a moral code of conduct.

Courtly love and the notion of domnei were often the subjects of troubadours, and could be typically found in artistic endeavors such as lyrical narratives and poetic prose of the time. Since marriage was commonly nothing more than a formal arrangement,[5] courtly love sometimes permitted expressions of emotional closeness that may have been lacking from the union between husband and wife.[6] In terms of courtly love, "lovers" did not necessarily refer to those engaging in sexual acts, but rather, to the act of caring and to emotional intimacy.

The bond between a knight and his Lady, or the woman of typically high stature of whom he served, may have escalated psychologically but seldom ever physically.[7] For knighthood during the Middle Ages, the intrinsic importance of a code of conduct was in large part as a value system of rules codified as a guide to aid a knight in his capacity as champion of the downtrodden, but especially in his service to the Lord.

In the context of dutiful service to a woman of high social standing, ethics designated as a code were effectively established as an institution to provide a firm moral foundation by which to combat the idea that unfit attentions and affections were to ever be tolerated as "a secret game of trysts" behind closed doors. Therefore, a knight trained in the substance of "chivalry" was instructed, with especial emphasis, to serve a lady most honorably, with purity of heart and mind. To that end, he committed himself to the welfare of both Lord and Lady with unwavering discipline and devotion, while at the same time, presuming to uphold core principles set forth in the code by the religion by which he followed.[7]

Religious meditations upon the Virgin Mary were partially responsible for the development of chivalry as an ethic and lifestyle: the concept of the honor of a lady and knightly devotion to her, coupled with an obligatory respect for all women, factored prominently as central to the very identity of medieval knighthood. As knights were increasingly emulated, eventual changes were reflected in the inner-workings of feudal society. Members of the aristocracy were schooled in the principles of chivalry, which facilitated important changes in attitudes regarding the value of women.[8]

Behaviorally, a knight was to regard himself towards a lady with a transcendence of premeditated thought—his virtue ingrained within his character. A chevalier was to conduct himself always graciously, bestowing upon her the utmost courtesy and attentiveness. He was to echo shades of this to all women, regardless of class, age, or status.[9] Over time, the concept of chivalry and the notion of the courtly gentleman became synonymous with the ideal of how love and romance should exist between the sexes. Through the timeless popularization in art and literature of tales of knights and princesses, kings and queens, a formative and long standing (sub) consciousness helped to shape relationships between men and women.

De amore or *The Art of Courtly Love*, as it is known in English, was written in the 12th century. The text is widely misread as permissive of extramarital affairs. However, it is useful to differentiate the physical from without: romantic love as separate and apart from courtly love when interpreting such topics as: "Marriage is no real excuse for not loving", "He who is not jealous cannot love", "No one can be bound by a double love", and "When made public love rarely endures".[10]

Some believe that romantic love evolved independently in multiple cultures. For example, in an article presented by Henry Grunebaum, he argues "therapists mistakenly believe that romantic love is a phenomenon unique to Western cultures and first expressed by the troubadours of the Middle Ages."[11]

The more current and Western traditional terminology meaning "court as lover" or the general idea of "romantic love" is believed to have originated in the late nineteenth and early twentieth centuries, primarily from that of the French culture. This idea is what has spurred the connection between the words "romantic" and "lover," thus coining English phrases for romantic love such as "loving like the Romans do." The precise origins of such a connection are unknown, however. Although the word "romance" or the equivalents thereof may not have the same connotation in other cultures, the general idea of "romantic love" appears to have crossed cultures and been accepted as a concept at one point in time or another.

Types

Romantic love is contrasted with platonic love, which in all usages, precludes sexual relations, yet only in the modern usage does it take on a fully asexual sense, rather than the classical sense, in which sexual drives are sublimated. Sublimation tends to be forgotten in casual thought about love aside from its emergence in psychoanalysis and Nietzsche.

Unrequited love can be romantic in different ways: comic, tragic, or in the sense that sublimation itself is comparable to romance, where the spirituality of both art and egalitarian ideals is combined with strong character and emotions. Unrequited love is typical of the period of romanticism, but the term is distinct from any romance that might arise within it.[12]

Romantic love may also be classified according to two categories, "popular romance" and "divine or spiritual" romance:

Popular romance
: may include but is not limited to the following types: idealistic, normal intense (such as the emotional aspect of "falling in love"), predictable as well as unpredictable, consuming (meaning consuming of time, energy and emotional withdrawals and bids), intense but out of control (such as the aspect of "falling out of love") material and commercial (such as societal gain mentioned in a later section of this article), physical and sexual, and finally grand and demonstrative.

Divine (or spiritual) romance
: may include, but is not limited to these following types: realistic, as well as plausible unrealistic, optimistic as well as pessimistic (depending upon the particular beliefs held by each person within the relationship.), abiding (e.g. the theory that each person had a predetermined stance as an agent of choice; such as "choosing a husband" or "choosing a soul mate."), non-abiding (e.g. the theory that we do not choose our actions, and therefore our romantic love involvement has been drawn from sources outside of ourselves), predictable as well as unpredictable, self-control (such as obedience and sacrifice within the context of the relationship) or lack thereof (such as disobedience within the context of the relationship), emotional and personal, soulful (in the theory that the mind, soul, and body, are one connected entity), intimate, and infinite (such as the idea that love itself or the love of a god or God's "unconditional" love is or could be everlasting)[13]

In philosophy

Greek philosophers and authors have had many theories of love.

Plato

Some of these theories are presented in Plato's *Symposium*. Six Athenian friends, including Socrates, drink wine and each give a speech praising the deity Eros. When his turn comes, Aristophanes says in his mythical speech that sexual partners seek each other because they are descended from beings with spherical torsos, two sets of human limbs, genitalia on each side, and two faces back to back. Their three forms included the three permutations of pairs of gender (i.e. one masculine and masculine, another feminine and feminine, and the third masculine and feminine) and they were split by the gods to thwart the creatures' assault on heaven, recapitulated, according to the comic playwright, in other myths such as the Aloadae.[14]

This story is relevant to modern romance partly because of the image of reciprocity it shows between the sexes. In the final speech before Alcibiades arrives, Socrates gives his encomium of love and desire as a lack of being, namely, the being or form of beauty.

French philosopher Gilles Deleuze linked this idea of love as a lack mainly to Sigmund Freud, and Deleuze often criticized it.

In *How to Make Good Decisions and Be Right All the Time*, British writer Iain King tried to establish rules for romance applicable across most cultures. He concluded on six rules, including:

1. Do not flirt with someone unless you might mean it.
2. Do not pursue people who you are not interested in, or who are not interested in you.
3. In general, express your affection or uncertainty clearly, unless there is a special reason not to.[15]

René Girard

Though there are many theories of romantic love—such as that of Robert Sternberg, in which it is merely a mean combining liking and sexual desire—the major theories involve far more insight. For most of the 20th century, Freud's theory of the family drama dominated theories of romance and sexual relationships. This gave rise to a few counter-theories. Theorists like Deleuze counter Freud and Jacques Lacan by attempting to return to a more naturalistic philosophy:

René Girard argues that romantic attraction is a product of jealousy and rivalry—particularly in a triangular form.

Girard, in any case, downplays romance's individuality in favor of jealousy and the love triangle, arguing that romantic attraction arises primarily in the observed attraction between two others. A natural objection is that this is circular reasoning, but Girard means that a small measure of attraction reaches a critical point insofar as it is caught up in mimesis. Shakespeare's *A Midsummer Night's Dream*, *As You Like It*, and *The Winter's Tale* are the best known examples of competitive-induced romance.[16]

Girard's theory of mimetic desire is controversial because of its alleged sexism. This view has to some extent supplanted its predecessor, Freudian Oedipal theory. It may find some spurious support in the supposed attraction of women to aggressive men. As a technique of attraction, often combined with irony, it is sometimes advised that one feign toughness and disinterest, but it can be a trivial or crude idea to promulgate to men, and it is not given with much understanding of mimetic desire in mind. Instead, cultivating a spirit of self-sacrifice, coupled with an attitude of appreciation or contemplation, directed towards the other of one's attractions, constitutes the ideals of what we consider to be true romantic love. Mimesis is always the desire to possess, in renouncing it we offer ourselves as a sacrificial gift to the other.[17]

Mimetic desire is often challenged by feminists, such as Toril Moi,[18] who argue that it does not account for the woman as inherently desired.

Though the centrality of rivalry is not itself a cynical view, it does emphasize the mechanical in love relations. In that sense, it does resonate with capitalism and cynicism native to post-modernity. Romance in this context leans more on fashion and irony, though these were important for it in less emancipated times. Sexual revolutions have brought change to these areas. Wit or irony therefore encompass an instability of romance that is not entirely new but has a more central social role, fine-tuned to certain modern peculiarities and subversion originating in various social revolutions, culminating mostly in the 1960s.[19]

Arthur Schopenhauer

The process of courtship also contributed to Arthur Schopenhauer's pessimism, despite his own romantic success,[20] and he argued that to be rid of the challenge of courtship would drive people to suicide with boredom. Schopenhauer theorized that individuals seek partners who share certain interests and tastes, while at the same time looking for a "complement" or completing of themselves in a partner, as in the cliché that "opposites attract", but with the added consideration that both partners manifest this attraction for the sake of the species:

> "But what ultimately draws two individuals of different sex exclusively to each other with such power is the will-to-live which manifests itself in the whole species, and here anticipates, in the individual that these two can produce, an objectification of its true nature corresponding to its aims." --World as Will and Representation, Volume 2, Chapter XLIV

Other philosophers

Later modern philosophers such as La Rochefoucauld, David Hume and Jean-Jacques Rousseau also focused on morality, but desire was central to French thought and Hume himself tended to adopt a French worldview and temperament. Desire in this milieu meant a very general idea termed "the passions," and this general interest was distinct from the contemporary idea of "passionate" now equated with "romantic." Love was a central topic again in the subsequent movement of Romanticism, which focused on such things as absorption in nature and the absolute, as well as platonic and unrequited love in German philosophy and literature.

Philosophers and authors interested in the nature of love, which may not have been mentioned in this article are Jane Austen, Stendhal, George Meredith, Marcel Proust, D. H. Lawrence, Sigmund Freud, Jean-Paul Sartre, Simone de Beauvoir, Ernest Hemingway, Henry Miller, Gilles Deleuze, and Alan Soble.

In literature

In the following excerpt, from William Shakespeare's *Romeo and Juliet*, Romeo, in saying "all combined, save what thou must combine By holy marriage" implies that it is not marriage with Juliet that he seeks but simply to be joined with her romantically. "I pray That thou consent to marry us" implies that the marriage means the removal of the social obstacle between the two opposing families, not that marriage is sought by Romeo with Juliet for any other particular reason, as adding to their love or giving it any more meaning.

> "Then plainly know my heart's dear love is set On the fair daughter of rich Capulet: As mine on hers, so hers is set on mine; And all combined, save what thou must combine By holy marriage: when and where and how We met, we woo'd and made exchange of vow, I'll tell thee as we pass; but this I pray, That thou consent to marry us to-day."
>
> --Romeo and Juliet, Act II, Scene III

Romeo and Juliet parting on the balcony in Act III.

Shakespeare and Søren Kierkegaard share a similar viewpoint that marriage and romance are not harmoniously *in tune* with each other. In Shakespeare's *Measure for Measure*, for example, "...there has not been, nor is there at this point, any display of affection between Isabella and the Duke, if by affection we mean something concerned with sexual attraction. The two at the end of the play love each other as they love virtue."[21] Isabella needs love, and she may reject marriage with the Duke because he seeks to beget an heir with her for her virtues, and she is not happy with the limited kind of love that implies.

Shakespeare argues that marriage, because of its purity, simply cannot incorporate romance. The extramarital nature of romance is also clarified by John Updike in his novel *Gertrude and Claudius*, as well as by *Hamlet*. This same supposition of romance is also found in the film *Braveheart* or rather apparent in the example of Isabella of France's life.

Romance raises questions of emotivism (or in a more pejorative sense, nihilism) such as whether spiritual attraction, of the world, might not actually rise above or distinguish itself from that of the body or aesthetic sensibility.

While Buddha taught a philosophy of compassion and love, still in his philosophy of anatman or non-self spiritual appearances are of a piece with the world and essentially empty. The contradiction between compassion and anatman seems to be a part of Buddhism. In that case a seemingly negative insight can result in very different overall views, for example if one compares Buddha and Shakespeare with Friedrich Nietzsche.

Kierkegaard also addressed these ideas in works such as *Either/Or* and *Stages on Life's Way*.[22]

Tragedy and other social issues

The "tragic" contradiction between romance and society is most forcibly portrayed in literature, in Tolstoy's *Anna Karenina*, in Flaubert's *Madame Bovary*, and William Shakespeare's *Romeo and Juliet*. The female protagonists in such stories are driven to suicide as if dying for a cause of freedom from various oppressions of marriage.

Even after sexual revolutions, on the other hand, to the extent that it does not lead to procreation (or child-rearing, as it also might exist in same-sex marriage), romance remains peripheral though it may have virtues in the relief of stress, as a source of inspiration or adventure, or in development and the strengthening of certain social relations. It is difficult to imagine the tragic heroines, however, as having such practical considerations in mind.

Romance can also be tragic in its conflict with society. The Tolstoy family focuses on the romantic limitations of marriage, and Anna Karenina prefers death to being married to her fiancé, however this is because she is tired of waiting and being hidden away from public, when her fiance makes failed attempts to get his mother's approval of the marriage. Even being aristocrats did not make them both free, as the society was nevertheless equally binding for all. Furthermore, in the speech about marriage that is given in Kierkegaard's *Either/Or*, Kierkegaard attempts to show that it is because marriage is lacking in passion fundamentally, that the nature of marriage, unlike romance, is explainable by a man who has experience of neither marriage nor love.

Reciprocity of the sexes appears in the ancient world primarily in myth where it is in fact often the subject of tragedy, for example in the myths of Theseus and Atalanta. Noteworthy female freedom or power was an exception rather than the rule, though this is a matter of speculation and debate.[23]

Psychology

Many theorists attempt to analyze the process of romantic love.

Helen Fisher

Anthropologist Helen Fisher, in her book *Why We Love*,[24] uses brain scans to show that love is the product of a chemical reaction in the brain. Norepinephrine and dopamine, among other brain chemicals, are responsible for excitement and bliss in humans as well as non-human animals. She is famous for the use of MRI to study the brain activity of a person "in love", discovering the importance of the ventral tegmental area and the caudate nucleus in this biological drive.

Fisher concludes that these reactions have a genetic basis, and therefore love is a natural drive as powerful as hunger.

John Townsend

In his book *What Women Want, What Men Want*,[25] anthropologist John Townsend takes the genetic basis of love one step further by identifying how the sexes are different in their predispositions.

Townsend's compilation of various research projects concludes that men are susceptible to youth and beauty, whereas women are susceptible to status and security. These differences are part of a natural selection process where males seek many healthy women of childbearing age to mother offspring, and women seek men who are willing and able to take care of them and their children.

Karen Horney

Psychologist Karen Horney in her article "*The Problem of the Monogamous Ideal*",[26] indicates that the overestimation of love leads to disillusionment; the desire to possess the partner results in the partner wanting to escape; and the taboos against sex result in non-fulfillment. Disillusionment plus the desire to escape plus non-fulfillment result in a secret hostility, which causes the other partner to feel alienated. Secret hostility in one and secret alienation in the other cause the partners to secretly hate each other. This secret hate often leads one or the other or both to seek love objects outside the marriage or relationship.

Harold Bessell

Psychologist Harold Bessell in his book *The Love Test*,[27] reconciles the opposing forces noted by the above researchers and shows that there are two factors that determine the quality of a relationship.

Bessell proposes that people are drawn together by a force he calls "romantic attraction," which is a combination of genetic and cultural factors. This force may be weak or strong and may be felt to different degrees by each of the two love partners. The other factor is "emotional maturity," which is the degree to which a person is capable of providing good treatment in a love relationship. It can thus be said that an immature person is more likely to overestimate love, become disillusioned, and have an affair whereas a mature person is more likely to see the relationship in realistic terms and act constructively to work out problems.

Lisa M. Diamond

Romantic love, in the abstract sense of the term, is traditionally considered to involve a mix of emotional and sexual desire for another as a person. However, Lisa M. Diamond, a University of Utah psychology professor, proposes that sexual desire and romantic love are functionally independent[28] and that romantic love is not intrinsically oriented to same-gender or other-gender partners. She also proposes that the links between love and desire are bidirectional as opposed to unilateral. Furthermore, Diamond does not state that one's sex has priority over another sex (a male or female) in romantic love because her theory suggests it is as possible for someone who is homosexual to fall in love with someone of the other gender as for someone who is heterosexual to fall in love with someone of the same gender.[29] In her 2012 review of this topic, Diamond emphasized that what is true for men may not be true for women. According to Diamond, in most men sexual orientation is fixed and most likely innate, but in many women sexual orientation may vary from 0 to 6 on the Kinsey scale and back again.[30]

Martie Haselton

Martie Haselton, a psychologist at UCLA, considers romantic love a "commitment device", or mechanism that encourages two humans to form a lasting bond. She has explored the evolutionary rationale that has shaped modern romantic love and has concluded that long-lasting relationships are helpful to ensure that children reach reproductive age and are fed and cared for by two parents. Haselton and her colleagues have found evidence in their experiments that suggest love's adaptation. The first part of the experiments consists of having people think about how much they love someone and then suppress thoughts of other attractive people. In the second part of the experiment the same people are asked to think about how much they sexually desire those same partners and then try to suppress thoughts about others. The results showed that love is more efficient in pushing out those rivals than sex.[31]

University research

Research by the University of Pavia suggests that romantic love lasts for about a year, before being replaced by a more stable form of love called companionate love.[32] In companionate love, changes occur from the early stage of love to when the relationship becomes more established and romantic feelings seem to end. However, research from Stony Brook University in New York suggests that some couples keep romantic feelings alive for much longer.[33]

Major theories

These are the major theories associated with current research on romantic relationships, especially in the context of positive psychology.

Attachment patterns

As mentioned in the introduction, attachment styles that people develop as children can influence the way that they interact with partners in adult relationships, with secure attachment styles being associated with healthier and more trusting relationships than avoidant or anxious attachment styles.[34][35] Hazen and Shaver found that adult romantic attachment styles were similar to the categories of secure, avoidant, and anxious that had previously been studied in children's attachments to their caregivers, demonstrating that attachment styles are stable across the lifespan.[36] Later on, researchers distinguished between dismissive avoidant attachment and fearful avoidant attachment.[37] Others have found that secure adult attachment, leading to the ability for intimacy and confidence in relationship stability, is characterized by low attachment-related anxiety and avoidance, while the fearful style is high on both dimensions, the dismissing style is low on anxiety and high on avoidance, and the preoccupied style is high on anxiety and low on avoidance.[38]

Romantic love definition/operationalization

Singer (1984a,[39] 1984b,[40] 1987[41]) first defined love based on four Greek terms: *eros*, meaning the search for beauty; *philia*, the feelings of affection in close friendships, *nomos*, the submission of and obedience to higher or divine powers, and *agape*, the bestowal of love and affection for the divine powers. While Singer did believe that love was important to world culture, he did not believe that romantic love played a major role (Singer, 1987[41]). However, Susan Hendrick and Clyde Hendrick at Texas Tech University (1992,[42] 2009[43]) have theorized that romantic love will play an increasingly important cultural role in the future, as it is considered an important part of living a fulfilling life. They also theorized that love in long-term romantic relationships has only been the product of cultural forces that came to fruition within the past 300 years. By cultural forces, they mean the increasing prevalence of individualistic ideologies, which are the result of an inward shift of many cultural worldviews.

Passionate and companionate love

Researchers have determined that romantic love is a complex emotion that can be divided into either passionate or companionate forms.[44] Berscheid and Walster (1978[45]) and Hatfield (1988[46]) found that these two forms can co-exist, either simultaneously or intermittently. Passionate love is an arousal-driven emotion that often gives people extreme feelings of happiness, and can also give people feelings of anguish. Companionate love is a form that creates a steadfast bond between two people, and gives people feelings of peace. Scientists have described the stage of passionate love as "being on cocaine," since during that stage the brain releases the same neurotransmitter, dopamine, as when cocaine is being used. [47] It is also estimated that passionate love lasts for about twelve to eighteen months. [48] Psychologist, Robert Firestone, has a theory of the fantasy bond, which is what is mostly created after the passionate love has faded. A couple may start to feel really comfortable with each other to the point that they see each other as simply companions or protectors, but yet think that they are still in love with each other. [49] The results to the fantasy bond is the leading to companionate love. Hendrick and Hendrick (1995[50]) studied college students who were in the early stages of a relationship and found that almost half reported that their significant other was their closest friend, providing evidence that both passionate and companionate love exist in new relationships. Conversely, in a study of long-term marriages, researchers (Contreras, Hendrick, and Hendrick, 1996[51]) found that couples endorsed measures of both companionate love and passionate love and that passionate love was the strongest predictor of marital satisfaction, showing that both types of love can endure throughout the years.

The triangular theory of love

Psychologist Robert Sternberg (1986[52]) developed the triangular theory of love. He theorized that love is a combination of three main components: passion (physical arousal); intimacy (psychological feelings of closeness); and commitment (the sustaining of a relationship). He also theorized that the different combinations of these three components could yield up to seven different forms of love. These include popularized forms such as romantic love (intimacy and passion) and consummate love (passion, intimacy, and commitment). The other forms are liking (intimacy), companionate love (intimacy and commitment), empty love (commitment), fatuous love (passion and commitment), and infatuation (passion). Studies on Sternberg's theory love found that intimacy most strongly predicted marital satisfaction in married couples, with passion also being an important predictor (Silberman, 1995[53]). On the other hand, Acker and Davis (1992[54]) found that commitment was the strongest predictor of relationship satisfaction, especially for long-term relationships.

The self-expansion theory of romantic love

Researchers Arthur and Elaine Aron (1986[55]) theorized that humans have a basic drive to expand their self-concepts. Further, their experience with Eastern concepts of love caused them to believe that positive emotions, cognitions, and relationships in romantic behaviors all drive the expansion of a person's self-concept. A study following college students for 10 weeks showed that those students who fell in love over the course of the investigation reported higher feelings of self-esteem and self efficacy than those who did not (Aron, Paris, and Aron, 1995[56]).

Mindful relationships

Harvey and Ormarzu (1997[57]) developed a model of minding relationships with five key components: seeking to know and be known by the other; using knowledge learned in a relationship to enhance the relationship; accepting the other person; being motivated to continue this process of learning, enhancing, and accepting; and developing a sense of appreciation in the relationship. Each of these components is considered adaptive, however, nonadaptive steps to minding a relationship were also theorized by the research team. The five nonadaptive components include: one or both partners out of step in seeking to know and be known by the other; not using the knowledge learned in a relationship to enhance the relationship (or using that knowledge to hurt the other); low acceptance and respect for the other person; not being motivated to continue the process of learning, enhancing, and accepting; and failing to develop a sense of appreciation in a relationship. Gottman studies the components of a flourishing romantic relationship have been studied in the lab (1994;[58] Gottman & Silver, 1999[59]). He used physiological and behavioral measures during couples' interactions to predict relationship success and found that five positive interactions to one negative interaction are needed to maintain a healthy relationship. He established a therapy intervention for couples that focused on civil forms of disapproval, a culture of appreciation, acceptance of responsibility for problems, and self-soothing (Gottman, Driver, & Tabares, 2002[60]).

Relationship behaviors

The most recent research on romantic love and relationships focuses on behaviors that either sustain a relationship or aid in its dissolution. These behaviors can be considered either appetitive or aversive. Appetitive relationship processes are considered the promotion of positive relationship behaviors, as determined by psychologists Gable and Reis (2001,[61] 2003[62]). Aversive relationship processes are described as eliminating behaviors that have a negative effect on relationships (Gable and Reis 2001,[61] 2003[62]). This new research has also allowed relationship success to be predicted as a function of these appetitive and aversive processes. This is all related to research that shows that sharing positive life events with one's partner is related to greater relationship satisfaction and intimacy (Gable et al., 2004[63]). In research by Gable et al. (2003) appetitive (promotion of positive relationship behaviors) and aversive (elimination of negative relationship behaviors) processes are independent constructs. A specific type of appetitive processing, capitalization, leads to increased relationship satisfaction and intimacy when one member of the relationship tells the other about positive life events and receive quality reactions and feedback from the partner (Gable, Reis, Impett, & Asher, 2004[63]).

Applications

Awareness of major theories on positive romantic relationships and knowledge of proven findings that support them gives couples the tools to strengthen their relationships and allows single individuals to have the resources to build a flourishing relationship in the future. Access to information like this could contribute to the reduction of divorce rates, as well as producing happier and healthier home lives for many families. For example, though there appears to be a correlation between an increased divorce rate and premarital cohabitation, living with a person of romantic interest before marriage still appears to be a common and growing trend.[64] Knowledge of this is one way positive psych could help aid flourishing relationships.

In addition to the aforementioned factors, awareness would also provide the opportunity for people to better understand or empathize with those who may not illustrate the level of positivity found in these major theories. Knowing this information can help with coming to terms with someone that is particularly difficult in a given romantic relationship, and could help one aid them to a better outlook through this gain of knowledge. The attachment style of individuals has a strong influence on the way future relationships are created and harnessed. While those with a secure attachment style fare better, one may be prone to more bumps in the road if having a disorganized style of attachment.

With a heightened awareness comes an upward spiral of positive relationships in general. Having younger individuals modeled by positive interactions would, in turn, greatly influence the probability of these individuals implementing such behaviors in their own social relationships.

It can be said that romantic love creates pair bonding between two individuals. It also increases the amount of available resources by combining those of two separate individuals thus leading to an increase in the reproductive fitness of potential offspring. This can be seen in the animal kingdom as well. For example, researchers observed the survival rate of mice offspring in father present and father absent environments and discovered that while both groups had approximately the same birth rate, with the father absent group even being a little bit higher, ultimately only 26% of the offspring in father absent group survived to emergence as opposed to the 81% of offspring that survived in the father present group.[65]

Controversies

Researchers such as Feeney and Noller question the stability of attachment style across the life span since studies that measured attachment styles at time points ranging from 2 weeks to 8 months found that 1 out of 4 adults' attachment style changed.[66] Furthermore, a study by Lopez and Gormley found that attachment styles could change during the first year of college and that changes to more secure attachment styles were associated with adjustments in self-confidence ratings and coping styles.[67] On the other hand, attachment styles in childhood mirror the ones found in adult romantic relationships.[68] In addition, research has shown that building interpersonal connections strengthens neural regulatory systems that are involved in emotions of empathy, enjoyment of positive social events, and stress management,[69][70] providing evidence that early social interactions affect adult relationships.

Another topic of controversy in the field of romantic relationships is that of domestic abuse. Following the theory that romantic love evolved as a byproduct of survival, it can be said that in some instances, it has turned into a maladaptation. Oxytocin is a neurophysical hormone produced in the brain. It is known to cause a decrease in stress response. It also can cause an increase in feelings of attachment. In the beginning stages of a romantic relationship, OT levels surge and then remain relatively stable over the duration of the relationship. The higher the surge of OT, the greater the likelihood is of partners staying together.[71] It plays an important role in increasing positive interpersonal behaviors such as trust, altruism, empathy, etc.[72] This response is not universal and can in fact, cause the opposite to occur depending on environment and individual. Individuals ranked high in rejection sensitivity exhibited aggressive tendencies and decreased willingness for cooperation, indicating a link between oxytocin and relationship maintenance.[73]

The feelings associated with romantic love function to ensure the greater reproductive fitness of individuals. The obligations of individuals in romantic relationships to preserve these bonds are based in kin selection theory, where by exhibiting aggressive behavior, a mate can use intimidation and dominance to ward off other potential predators, thus protecting the pair bond and their actual or potential offspring. This has however evolved to the point where it has become detrimental to the fitness of individuals; what is causing attachment to occur in a relationship, is now causing one partner to harm the other.

In the search for the root of intimate partner violence, intranasal oxytocin was administered to a control group and a group of participants with aggressive tendencies. Participants were then surveyed on how willing they were to engage in 5 behaviors towards their romantic partner. What they found was that oxytocin increased IPV inclinations only among the participants with a predisposition towards aggressive tendencies.[74] Oxytocin decreases trust and prosocial behavior in individuals with interpersonal difficulties. This, coupled with its role in relationship maintenance, illustrates that oxytocin serves to instill a sense of territoriality and protectiveness towards a mate.

"In the first place, I find it comical that all men are in love and want to be in love, and yet one never can get any illumination upon the question what the lovable, i.e., the proper object of love, really is." (*Stages* p. 48). Nietzsche, while he might answer negatively to the platonic theory of love as having a transcendent object, being a naturalist, was more interested intellectually in marriage than in romance, as evinced by the many aphorisms on marriage in *Human All Too Human*. In any case, Nietzsche is often taken as diametrically opposed to Kierkegaard, of whom there is often supposed mention in *Thus Spake Zarathustra* alongside Leo Tolstoy. (Shakespeare raises a similar criticism about the meaning of love in *Measure for Measure*, and *Love's Labors Lost* is often considered Shakespeare's encomium on love.)

Umschlagbild :

Experimentelles Niedrigkosten-Bedachungselement : auf einer Bambus-Unterkonstruktion wird Jute-Sackmaterial verlegt, unmittelbar nachdem es in einer dickflüssigen Mischung aus Bimssand, Zement und Wasser (bzw. Erde, Kalk und Wasser) getaucht wurde. Nach Glättung der Oberfläche entsteht der Eindruck einer Wellblech- oder Asbestzement-Deckung. (Siehe Abschnitt 6.2.2)

Cover illustration :

Experimental low cost roofing element : on a bamboo framework, jute sacking material is laid immediately after dipping it in a thick mixture of pumice-sand, cement and water (or soil, lime and water). After smoothening the surface, the roof resembles corrugated steel or asbestos cement sheeting. (See section 6.2.2)

1. EINLEITUNG

1.1 Zielsetzung

Der gebräuchliche Spruch, "ein Dach über dem Kopf haben", vermittelt ein Gefühl der Sicherheit und Behaglichkeit. Viele Wohnungsbaugesellschaften und Bausparkassen verwenden das Dach als Symbol, wobei "Dach" und "Wohnstätte" als Synonyme verstanden werden. Aber auch technisch ist das Dach der wichtigste Teil des Hauses: es kostet am meisten; gerechnet nach Fläche und Orientierung ist es der Teil, der den Elementen am meisten ausgesetzt ist, und es ist der Teil, der hauptsächlich für den Komfort im Haus und für Schäden durch Erdbeben und Wirbelstürme verantwortlich ist.

Jedoch trotz dieser Bedeutung des Daches ist es wahrscheinlich der meist vernachlässigte Teil in bezug auf Forschung und Entwicklung. So werden in Entwicklungsländern, abgesehen von herkömmlichen Bauwerken, immer mehr verzinktes Wellblech und, in geringerem Maße, Asbestzement verwendet, obwohl diese eine Anzahl von schwerwiegenden Nachteilen mit sich bringen.

Diese Überlegungen und die Tatsache, daß mangelhafte Bedachung in katastrophengefährdeten Regionen, wie Zentral-Amerika, Tausende von Leben gekostet hat, waren die Motivierung für diese Forschungsarbeit. Initiiert und finanziert wurde sie von der Deutschen Gesellschaft für Technische Zusammenarbeit (GTZ) GmbH im Rahmen der deutschen technischen Hilfe.

Zweck dieses neunmonatigen Forschungsprojektes war, alle verfügbaren Materialien über kostengünstige Bedachungen sowohl global als auch die Situation in Zentral-Amerika im Detail zu untersuchen, und auch Materialien, Bausysteme und Herstellungsmethoden zu identifizieren, die

- erdbeben- und hurrikanbeständig sind,
- für die gegebenen klimatischen Bedingungen geeignet sind,
- Kosten für Einfachwohnbau reduzieren helfen,
- für Selbsthilfe und genossenschaftliche Wohnbauprojekte angewandt werden können,
- maximalen Einsatz von lokalen Ressourcen ermöglichen,
- ausreichend dauerhaft sind und niedrige Instandhaltungskosten verursachen,
- örtlich hergestellt werden können, auch in kleinem Umfang.

Es muß betont werden, daß ein Forschungsbericht über Bedachungssysteme nie komplett sein kann. Die Vielfalt von Formen, Bauarten und Materialien, die verwendet werden, ist unbegrenzt. Das Ziel war jedoch, grundlegende Daten über die wichtigsten Aspekte von Bedachungsmaterialien und -konstruktionen in Entwicklungsländern vorzustellen und den Weg für weitere Forschung zu bahnen.

1. INTRODUCTION

1.1 Aim

The common phrase "to have a roof over one's head" communicates a sense of security and comfort. Many housing housing organizations and housing banks use the roof as a symbol, suggesting a synonymy of "roof" and "shelter". But even technically the roof is the most significant part of a house: it costs the most, by area and orientation it is the part most exposed to the elements, and it is the part primarily responsible both for indoor comfort and for damage suffered during earthquakes and hurricanes.

Yet despite the importance of the roof, it is probably the most neglected part in terms of research and development. Thus in developing countries, apart from traditional structures, corrugated galvanized iron and, to a lesser extent, asbestos cement are increasingly being used, even though they have a number of serious disadvantages.

These considerations, and the fact that deficient roofing in disaster prone regions, such as Central America, has cost thousands of lives, were the motivations behind this research study. It was initiated and financed by the German Agency for Technical Cooperation, Ltd. (GTZ) within the scope of German technical aid.

The object of the nine-month research project was to study all available material on low-cost roofing, both on a global scale as well as in detail on the situation in Central America, and to identify materials, construction systems and production processes that:

- are earthquake and hurricane resistant,
- are appropriate for the given climatic conditions,
- help to reduce costs for low-cost housing,
- can be implemented in self-help and cooperative housing schemes,
- make maximum use of local resources,
- have sufficient durability and low maintenance costs,
- can be produced locally even on a small scale.

It must be stressed that a research report on roofing systems can never be complete. The diversity of shapes, constructions and materials used is unlimited. However, the object was to present basic data on the most important aspects of low-cost roofing in developing countries and to prepare the way for deeper research.

1.2 Verfahrensweise

Während dieses Forschungsprojektes war das Sammeln von Daten die Hauptaufgabe. Dies geschah hauptsächlich durch

- bibliographische Ermittlungen
- Schriftverkehr mit verschiedenen Instituten und Sachverständigen in einer Anzahl verschiedener Länder
- Besuche von interessanten Baustellen und Produktionseinheiten für Baumaterialien, persönliche Kontakte mit Experten sowohl in Entwicklungsländern als auch in Industrieländern.

Zwischen Juni und Oktober 1979 wurden im Hauptsitz von ICAITI in Guatemala kleinere Versuche unternommen, um die Durchführbarkeit von Ideen für neue Entwicklungen, die sich aus der Datensammlung und -evaluierung ergaben, zu testen. Notwendigerweise konnte dies nur sporadisch sein, und das alleinige Ziel war, so viele verschiedene Materialien und Systeme auszuprobieren, wie es die Zeit erlaubte. Dies zeigte sich als eine wertvolle Methode, eine große Auswahl von Problemen und Möglichkeiten neuer Lösungen zu studieren, um die Ergebnisse und Empfehlungen zu qualifizieren.

Die Arbeit an diesem Projekt wurde zwischen den beiden Instituten geteilt, so daß ICAITI alle Daten über Zentral-Amerika sammelte und auswertete und die Einrichtungen sowie die Dokumentation der experimentalen Arbeit zur Verfügung stellte, während sich I.F.T. mit den übrigen Abschnitten, die grundsätzliche und detaillierte Informationen über Bedachungen in den Entwicklungsländern im allgemeinen behandeln, befaßte. Der größte Teil der experimentalen Arbeit, so wie die Formulierung der Schlußfolgerungen und Empfehlungen erfolgte gemeinsam. Das abschließende Arbeitsdokument wurde in Englisch geschrieben und danach von ICAITI in Spanisch und vom I.F.T. in Deutsch übersetzt. Die spanische Fassung wurde zur Verbreitung in Lateinamerika von ICAITI veröffentlicht.

1.2 Methodology

Throughout the research project, the collection of data was the major task. The means employed were primarily:

- bibliographic investigations,
- correspondence with various institutes and experts in a number of countries,
- visits to interesting project sites and production units for building materials, personal contacts with experts both in developing and industrialized countries.

Minor experimental work was undertaken between June and October 1979 at the headquarters of ICAITI in Guatemala, to test the feasibility of ideas for new developments arising from the data collection and evaluation. Of necessity this could only be sporadic and the sole aim was to try out as many different materials and systems as the time permitted. This proved to be an invaluable means of studying a wide range of problems and possibilities of new solutions, to qualify the conclusions and recommendations made.

The work on the project was divided between the two institutes, such that ICAITI collected and evaluated all data on Central America and provided the facilities and documentation of experimental work, while I.F.T. was concerned with the other sections, which involved basic and detailed data on roofing with respect to developing countries in general. Most of the experimental work as well as the formulation of conclusions and recommendations were carried out jointly. The final working document was written in English and subsequently translated into Spanish and German by ICAITI and I.F.T. respectively. The Spanish version was published by ICAITI for dissemination in Latin America.

2. DÄCHER FÜR DEN WOHNUNGSBAU

2.1 Herkömmliche Dachtypen

Die Hauptfunktion des Daches ist, Wohn- und Arbeitsraum zu überdecken und somit Schutz vor den Elementen zu geben. Dies kann durch unbegrenzte Varianten und Formen, Konstruktionssysteme und Materialien erreicht werden. Stark vereinfacht zeigt die folgende Zusammenfassung die grundlegenden Unterschiede, wobei ihre funktionalen Aspekte und geeigneten Verwendungszwecke, besonders im Zusammenhang mit dem sozialen Wohnungsbau, erläutert werden.

2.1.1 Flache Dächer

Bausysteme: Balken, massive Platten, leichte Platten

Abb. 2.1

Typische Materialien:

(a. Tragkonstruktionen, b. Dachdeckung, c. Feuchtigkeitsisolierung)

- Holz (a, b)
- Stahlbeton (a, b)
- Stahl (a)
- Profilmetallplatten (a, b, c)
- Profilasbestzementplatten (a, b, c)
- Erde, auch grastragender Humus (b)
- Verschiedene Spanplatten/Verbundplatten (b)
- Dachpappe (c)
- Bitumen (c)
- Anstriche (c)

Bemerkungen:

- Nach Definition sind flache Dächer weniger als 10° zur Horizontalen geneigt. Für den Abfluß von Regenwasser ist eine Neigung von mindestens 2° nötig.
- Häufig vorkommender Dachtyp in überwiegend trocken-heißen Zonen, mit unbedeutenden Niederschlägen.
- Nicht geeignet für Hurrikanzonen, da die Sogwirkung von Windkräften Dächer abreißen kann.
- Zusätzlicher Lebensraum auf dem Dach (Haushaltaktivitäten, Schlafen bei Nacht).
- Leichte vertikale Erweiterung des Gebäudes.
- Dachplatten mit Gefälle und großen Überlappungen zu verlegen.

2. ROOFS FOR HOUSING

2.1 Common Roof Types

The prime function of the roof is to cover dwelling and working space and thus provide shelter from the elements. This is achieved by an unlimited variety of shapes, construction systems and materials. Generalizing to a large extent, the following summary of roof types shows their basic differences, discussing briefly their functional aspects and appropriate uses, especially in the context of low-cost housing.

2.1.1 Flat Roofs

Structural system: beams, girders, slabs, sheets

Fig. 2.1

Typical Materials:

(a. Supporting structure, b. Roof decking, c. Waterproofing)

- Timber (a, b)
- Reinforced concrete (a, b)
- Steel (a)
- Profiled metal sheets (a, b, c)
- Profiled asbestos cement sheets (a, b, c)
- Soil — also grass-bearing humus (b)
- Diverse composite building boards (b)
- Roofing felt (c)
- Bitumen (c)
- Liquid finishes (c)

Comments:

- By definition, flat roofs have inclinations of less than 10° to the horizontal. For rainwater run-off at least 2° slope necessary.
- Common roof type in predominantly hot dry areas, with inconsiderable precipitation.
- Not appropriate for hurricane prone areas, as wind forces tend to pull off roof by suction.
- Additional living space on roof (household activities, sleeping at night).
- Easy vertical extensions of building.
- Sheet decking must be laid in falls with large overlaps.

2.1.2 Pultdach, Satteldach und Walmdach

Bausysteme: Sparren, Pfetten, Binder, leichte Platten, massive Platten.

Abb. 2.2

Typische Materialien:

(a. Tragkonstruktion, b. Dachdeckung, c. Feuchtigkeitsisolierung)

- Holz (a, b)
- Bambus (a, b)
- Stahlbeton (a, b)
- Stahl (a)
- Profilmetallplatten (a, b, c)
- Profilasbestzementplatten (a, b, c)
- Ziegel (b, c)
- Verschiedene pflanzliche Baustoffe, wie Stroh oder Matten (b)
- Verschiedene Spanplatten/Verbundplatten (b)
- Dachpappe (c)
- Bitumen (c)
- Anstriche (c)

Bemerkungen:

- Hauptsächlich in feuchtwarmen Zonen mit bedeutenden Niederschlägen.
- Geeignet für Hurrikanzonen, wenn Dachneigungen über 30° (ungefähr 1 : 1.7 oder 58%); flachere Dächer verursachen Sogkräfte, welche bei 10° am stärksten sind.
- Große Dachüberstände sind in Hurrikanzonen nicht geeignet, jedoch von Vorteil, um Wände und Öffnungen zu beschatten und um Abfluß von Regenwasser vom Gebäude fernzuhalten.
- Geringe Neigungen sind üblich, weil sie wirtschaftlich sind: weniger Baumaterial, weniger Dachfläche (demnach weniger Dachmaterial), Erweiterung in Gefälle-

2.1.2 Single Pitched, Gabled and Hipped Roofs

Structural system: rafters, purlins, trusses, sheets, slabs

Fig. 2.2

Typical Materials:

(a. Supporting structure, b. Roof decking, c. Waterproofing)

- Timber (a, b)
- Bamboo (a, b)
- Reinforced concrete (a, b)
- Steel (a)
- Profiled metal sheets (a, b, c)
- Profiled asbestos cement sheets (a, b, c)
- Burnt clay tiles (b, c)
- Diverse plant materials as thatch or matting (b)
- Diverse composite building boards (b)
- Roofing felt (c)
- Bitumen (c)
- Liquid finishes (c)

Comments:

- Used predominantly in warm humid regions with significant precipitation.
- Appropriate for hurricane prone areas, if roof slopes exceed 30° (about 1 : 1.7 or 58%); flatter roofs create suction forces which are strongest at 10° pitch.
- Wide overhangs disadvantageous in hurricane areas, but advantageous for shading of walls and openings and for discharging rainwater run-off clear of building.
- Low pitches are common, because they are economical: less wall construction material, less roof surface (consequently less roofing materials), extensions in direction of fall (e.g. verandahs) possible with sufficient head height.
- Each decking has its own appropriate slope (see Section 3.5).

richtung (z.B. Veranden) mit genügend Kopfhöhe möglich.
- Jede Deckungsart hat ihre erforderliche Mindestneigung (siehe Teil 3.5).
- Gefahr von Wasserdurchdringung, wenn die Neigung im Verhältnis zur Überlappung nicht ausreichend ist.
- Walmdächer schützen alle Wände (während Satteldächer die Stirnwände ungeschützt lassen), sind sparsam an Wandfläche und Kosten, leisten weniger Widerstand gegen Wind, sind aber schwieriger zu konstruieren.
- Angrenzende Satteldächer mit internen horizontalen Dachrinnen sind problematisch, selbst mit leichter Neigung: Ansammlung von Schmutz verhindert den Wasserabfluß, bringt schnellen Verfall des Dachmaterials.

2.1.3 Gekrümmte Dächer

Bausysteme: Gewölbe, Kuppeln, Zugbandbögen oder Schalenkonstruktionen.

Abb. 2.3

Typische Materialien:

(a. Tragkonstruktionen, b. Dachdeckung, c. Feuchtigkeitsisolierung)

- Stabilisierte Erdblöcke (a, b)
- Ziegel (a, b)
- Stahlbeton/Ferrozement (a, b)
- Holz (a, b)
- Bambus (a)
- Stahl (a)
- Profilmetallplatten (a, b, c)
- Profilasbestzementplatten (a, b, c)
- Faserverstärkte Kunststoffe (a, b, c)
- Verschiedene pflanzliche Baustoffe wie Stroh oder Matten (b)
- Verschiedene Spanplatten/Verbundplatten (b)
- Dachpappe (c)
- Bitumen (c)
- Anstriche (c)

- Water penetration occurs when slope in relation to overlap of decking elements is insufficient.
- Hipped roofs protect all walls (while gabled roofs leave end walls exposed), economize on wall area and cost, provide less obstruction to strong winds, but are more difficult to construct.
- Adjoining gabled roofs with internal horizontal gutters are problematic even with slight inclination: accumulation of dirt preventing passage of water, rapid deterioration of roofing fabric.

2.1.3 Curved Roofs

Structural System: true arches, domes, bow-string or shell structures.

Fig. 2.3

Typical Materials:

(a. Supporting structure, b. Roof decking, c. Waterproofing)

- Stabilized soil blocks (a, b)
- Burnt clay bricks (a, b)
- Reinforced concrete/Ferrocement (a, b)
- Timber (a, b)
- Bamboo (a)
- Steel (a)
- Profiled metal sheets (a, b, c)
- Profiled asbestos cement sheets (a, b, c)
- Fibre reinforced synthetic materials (a, b, c)
- Diverse plant material as thatch or matting (b)
- Diverse composite building boards (b)
- Roofing felt (c)
- Bitumen (c)
- Liquid finishes (c)

Bemerkungen:

- Gemauerte Bögen und Kuppeln sind für Erdbebenzonen höchst ungeeignet, während Zugband-Bögen und Schalenkonstruktionen ideal sein können.
- Schalenkonstruktionen sind normalerweise teuer, da sie meistens fortgeschrittene Technologie und Materialien von hoher Qualität (z.B. Spannbeton) erfordern. Einige Schalenkonstruktionen (z.B. Hartmoltopren-"Iglus" für Notwohnungen) sind schnell aufgebaut und verhältnismäßig billig, aber völlig ungeeignet für Behausungen.

2.1.4 Andere Dacharten

Die drei oben besprochenen prinzipiellen Dacharten umfassen alle gängigen Dacharten des Niedrigkosten-Wohnungsbaus in der Dritten Welt. Es gibt jedoch eine große Anzahl anderer Dachsysteme, welche für Kurzzeit- und Permanentbehausung angewandt werden, welche jedoch zu selten vorkommen, um deren detaillierte Beschreibung zu rechtfertigen.

Beispiele sind:

- Zugkonstruktionen
  die aus einem System von starken Membranen über Kabeln oder Seilen bestehen; große Spannweiten; verhältnismäßig wirtschaftlich, aber aerodynamisch unstabil mit leichter Decke; hauptsächlich für temporäre Bauten angewandt.
- Raumfachwerk-Dächer
  bestehend aus dreidimensionalen, dreieckigen Tragelementen; große horizontale Stabilität; leichte Dachdeckung; komplizierte, teure Bauweise; nur für sehr große Spannweiten geeignet.
- Faltplattendächer
  welche aus einer Serie von gleichen Platten mit geraden, steifen Verbindungen bestehen, deren Stärke in den aussteifenden Falzen, Gegenfalzen und stützenden Querscheiben liegt; geeignet für Vorfertigung; verhältnismäßig neues Bausystem mit unkonventionellen Formen, die eine verbreitete Anwendung bei Wohnungsbauprojekten verhindern.
- Luftgetragene Dächer
  meist kugel-, halbkugel- oder zylinderförmig, die grundlegend aus zwei Typen bestehen: der eine mit höherem internem Luftdruck als der der umgebenden Atmosphäre, und der andere aus aufgeblasenen Rohrelementen, bei dem das Innere nicht unter Druck steht; nur von Interesse für provisorische Unterkünfte oder bei großen Spannweiten; bedarf hochentwickelter Geräte und Technologie; sehr anfällig für Schäden.

Die Liste kann mit unbegrenzten freien Formen und Kombinationen der beschriebenen Dachtypen erweitert werden. Sogenannte "Anti-Dächer", wie z.B. Laubbäume (die im Sommer durch ihre Blätter Schatten spenden und die Sonne im Winter hindurchlassen) sind nur für Außenflächen von Interesse und haben keine Bedeutung für den Niedrigkosten-Wohnungsbau.

Comments:

- Masonry arches and domes are highly inappropriate for earthquake prone regions, while bow-string and shell structures can be ideal.
- Shell structures are usually expensive, since they often involve advanced technology and high quality materials (e.g. prestressed concrete). Some shells (e.g. polyurethane "igloos" for emergency housing) are quickly erected and relatively cheap, but totally unsuited as dwellings.

2.1.4 Other Roof Types

The three basic roof types dealt with above include all common roofs found in third world low-cost housing schemes. There are, however, a great number of other roofing systems, which may have applications in temporary or permanent housing, but are too rare to justify detailed descriptions.

Examples are:

- Tensile roofs
  using a system of tough membranes on cables or ropes; wide spans; relatively economical but aerodynamically unstable with light deck; generally used for temporary structures.
- Space frame roofs
  consisting of three-dimensionally triangulated supporting members; great lateral rigidity; light roof decking; complicated, expensive structure; appropriate only for extremely large spans.
- Folded plate roofs
  which consist of series of equal plates with straight, rigid junctions, deriving their strength from stiffening folds, counterfolds and supporting diaphragms; suitable for prefabrication; relatively new structural system with unconventional forms hindering wider use in housing schemes.
- Air-supported roofs
  usually of spherical, semispherical or cylindrical shapes, comprising basically two types: one having an internal air pressure greater than the ambient atmospheric pressure and one having inflated tubular members and unpressurized interior; only of interest as temporary dwellings or for large spans; requires sophisticated equipment and technology; highly susceptible to damage.

The list can be augmented by unlimited free forms and combinations of the described roof types. So-called "anti-roofs", such as deciduous plants (providing shade by their leaf cover in summer and allowing the sun in during winter) are of interest only for outdoor spaces and have no significant applications in low-cost housing design.

2.2 Gestaltungskriterien des Daches

Es wird generell angenommen, daß der Entwurf von Dächern in einer betreffenden Zone allein durch klimatische Anforderungen bestimmt wird und daß die vorhandenen Materialien die geeignetste Anwendung erfahren. Dies trifft zweifellos zu bei den meisten herkömmlichen Dachtypen, aber, wie Amos Rapoport in seinem Buch "House Form and Culture" darauf hinweist, können ähnliche klimatische Bedingungen und Materialien in verschiedenen geographischen und kulturellen Umgebungen völlig verschiedene Entwurfslösungen hervorbringen, welche gleichermaßen funktional sind. Seine Erklärung: "Die Unterschiede verschiedener Gebäudetypen in verschiedenen Regionen zeugen von Unterschieden in bezug auf vorhandene Kulturen, Rituale, Lebensweisen, Gesellschaftsstrukturen, Klimabedingungen und Landschaften, sowie Materialien und Technologie, während Ähnlichkeiten Bereiche aufzeigen, in denen nicht nur all diese Faktoren zufällig übereinstimmen, sondern auch einige grundlegende Übereinstimmungen in den Bedürfnissen und Wünschen des Menschen."

Demnach ist es klar, daß die Hausform — und somit auch Dachgestaltung — aus höchst komplizierten Entwurfskriterien resultiert, wobei, wie Rapoport meint, soziokulturelle Einflüsse vor den physikalischen Bestimmungsfaktoren rangieren.

Beispiele von sozio-kulturellen Entwurfskriterien sind:
- Religion
- Familien- und Sippenstruktur
- Lebensrhythmus
- Verteidigung
- Bautraditionen
- Zeitdimensionen
- Vermischung von Kulturen
- Einstellung gegenüber der Umwelt
- Mobilität

Diese Kriterien werden zum Teil in Abschnitt 3.1.1 „Örtliche Traditionen", besprochen.

Die Tatsache, daß Mobilität, als eines der wichtigen Entwurfskriterien, weit auseinandergehende Formen hervorgerufen hat (z.B. arabische Zelte, mongolische Yurts, indianische Tipis), zeigt, daß der Dachentwurf nicht einer einzigen Ursache zugeschrieben werden kann.

Die besondere Bedeutung von sozio-kulturellen Faktoren beim Dachentwurf führt oft zu physikalisch unzureichenden Lösungen. Zum Beispiel leben viele Stämme in der Amazonen-Region in großen Gemeinschaftshäusern ("malocas"), welche außerordentlich groß sind und dickwandige Bauweise für Stabilität und Dauerhaftigkeit erfordern, aber als Folge daraus so viel Wärme aufnehmen, so daß sie im Sommer nicht bewohnbar sind. Die wirtschaftlichen Aktivitäten der Hidatsa aus dem Missouri Valley, die im Sommer Bauern und im Winter Büffeljäger waren, lebten während des Sommers in massiven, wärmespeichernden Behausungen und in transportablen Zelten im Winter, obwohl klimatisch das Gegenteil geeigneter wäre.

2.2 Factors Influencing Roof Design

It is generally believed that the design of roofs in a certain region is governed solely by the climatic requirements and makes the most appropriate use of available materials. This is undoubtedly true for most traditional roof designs, but as Amos Rapoport in his book "House Form and Culture" points out, similar climatic conditions and materials in different geographical and cultural settings can generate completely dissimilar design solutions, which are equally functional. His explanation: "The differences between the types of buildings in different areas are evidence of differences in culture, rituals, ways of life, and social organization, climates and landscapes, and materials and technology available, while the similarities are evidence not only of areas where some or all of these factors have coincided, but also of some basic consistancies in man's needs and desires".

Thus it is clear that house form — and consequently roof design — results from a highly complex set of design criteria, whereby, as Rapoport maintains, socio-cultural forces outweigh physical determinants.

Examples of socio-cultural design criteria are:
- religion
- family and clan structure
- occupancy patterns
- defense
- building traditions
- time dimensions
- mixture of cultures
- attitude towards the environment
- mobility

These criteria are discussed to some extent in section 3.1.1 Local Traditions.

The fact that mobility, as one important design criterion, has induced greatly differing forms (e.g. Arab tents, Mongol yurts, Indian tepees) shows that roof design cannot be attributed to a single cause.

The predominance of socio-cultural factors in roof design occasionally lead to physically inadequate solutions. For example, many tribes in the Amazon area live in large communal houses ("malocas"), which are extremely large, requiring massive constructions for stability and durability, but as a result absorb so much heat that they have to be abandoned during the summer. The economic activity of the Hidatsa of the Missouri Valley, who were agriculturalists in summer and buffalo hunters in winter, causes them to live in heavy, heat absorbing dwellings in the hot months and light, transportable tents during the cold season, although climatically the reverse would be appropriate.

The principal physical determinants and requirements are:

- climate
  (exclusion of rain, wind and solar radiation, prevention of excessive heat penetration or entry of cold air, provision of shade for exterior walls and openings),

a. Behausungen aus einem Material (Schilf). Links: Uru-Haus, Titicaca-See, Peru. Rechts: Sumpf-Araber-Haus, Irak-Iran Grenzland.

Abb. 2.5 bis 2.7 zeigen jeweils die gleiche Dachform und -konstruktion, trotz der grundsätzlichen sozio-kulturellen Unterschiede zwischen Lateinamerika, Afrika und Ozeanien.

Fig. 2.5 to 2.7 each show the same roof form and construction, despite the basic socio-cultural differences between Latin America, Africa and Oceania.

2.5

Die wichtigsten physikalischen Bedingungen und Erfordernisse sind:

- Klima
  (Ausschließung von Regen, Wind und Sonne, Verhinderung übermäßiger Wärmeeinwirkung bzw. Eindringen von kalter Luft, Beschattung der äußeren Wände und Öffnungen),
- Umwelt
  (Lärmschutzmaßnahmen, Ausschließung von Schmutz, Staub und fallenden Gegenständen, Schutz vor Einbrechern, Einfügung in die Landschaft),
- natürliche Risiken
  (Fähigkeit, Erdbeben und Wirbelstürmen zu widerstehen, Widerstand gegen und Verhinderung von schneller Feuerausbreitung),
- Materialien
  (Wirtschaftlichkeit, leichtes Handhaben, Errichtung und Instandhaltung, Dauerhaftigkeit, günstige ästhetische Erscheinung),
- Gesundheitsaspekte
  (Verhinderung von feuchten, zugigen und toxischen Bedingungen, Verhinderung von Ungezieferbrutstätten).

Die Bestimmungsfaktoren von Dachentwürfen sind vielfältig, was aber nicht heißt, daß alle relevanten Kriterien für jeden Dachtyp berücksichtigt worden sind, selbst wenn traditionelle Bauweisen über Jahrzehnte hin entwickelt und verfeinert wurden.

2.6

- environment
  (provision of sound insulation, exclusion of dirt, dust and falling objects, provision of no means for intruders to break into building, harmonization with landscape),
- natural hazards
  (capability of withstanding earthquakes and hurricanes, resistance to and prevention of rapid spread of fire),
- materials
  (economy, ease of handling, installation and maintenance, durability, aesthetical acceptability),
- health aspects
  (avoidance of moist, draughty or toxic conditions, no provision of nesting places for vermin).

The determinants of roof design are manyfold, but this does not imply that all relevant factors have been considered in each roof type, even if traditional structures have been developed and refined over centuries. Health aspects generally receive the least attention, as for instance, in New Guinea dirt dropping from thatched roofs cause chronic allergic lung diseases, or in Venezuela primitive house constructions harbour insects carrying "chagos".

It is also important to note, that change of materials does not necessarily alter form.

2.7

3. ENTWURFSÜBERLEGUNGEN

3.1 Örtliche Traditionen und Bauvorschriften

Wie im vorherigen Abschnitt verdeutlicht wurde, müssen technische oder klimatologische Überlegungen für den Entwurf von Dächern in der Wertigkeit hinter denen der örtlichen sozialen und gesellschaftlichen Anforderungen rangieren. Diese Aspekte sind jedoch zu komplex, um sie mit ausreichender Gründlichkeit auf globaler Ebene zu behandeln. Um den Umfang und die Art der Fragen, die daraus hervorgehen, zu zeigen, werden einige der wichtigsten nachfolgend besprochen.

3.1.1 Örtliche Traditionen

In den meisten Fällen werden die Entwurfskriterien für Dachkonstruktionen als selbstverständlich erachtet. Die meisten traditionsorientierten Gesellschaften widersetzen sich jedweder Änderung, und ihr Ziel ist es, nur den Standard der gut gebauten Häuser ihrer Umgebung zu erreichen. Jedoch, da Traditionen ihre Kontinuität verloren haben (durch Mischen von Kulturen, Änderungen in der ökonomischen Struktur, politische Einflüsse und dergleichen), ist die Funktion der Dächer und die Art, in der sie gebaut werden können, so vielfältig, daß nur eine gründliche Überlegung und exakte Definierung der verschiedenen Erfordernisse einen zufriedenstellenden Dachentwurf garantieren.

Funktionen des Daches

a. Soll das Dach, teilweise oder ganz, ein temporäres oder dauerhaftes Bauwerk sein?
Temporäre Dächer können im Falle von Beschattungselementen, Öffnungen (als Eingang oder Rauchabzug oder für Luft und Licht) und transportablen Gebäuden nötig sein.

b. Was soll das Dach schützen: Menschen, Tiere oder Güter?
Welche Aktivitäten sollen unter dem Dach stattfinden?

Beispiele von Aktivitäten, die die Dachkonstruktion beeinflussen können, sind:

- Lebensweisen im Zusammenhang mit, zum Beispiel, Schlafen, Lesen, Unterhalten, Spielen, Musikhören, Gäste empfangen, Kranke betreuen, Beten, welches Aktivitäten sind, die thermalen Komfort sowie optische und akustische Intimität verlangen;
- Arbeit, wie Handwerk, Kleinindustrie, d.h. sowohl manuelle wie auch nichtmanuelle Tätigkeiten, die alle genügend Licht und thermalen Komfort benötigen;
- Kochen, mit oder ohne offenem Feuer, bedarf guter Ventilation und Öffnungen im Dach oder Schornstein;
- Baden, Waschen, Gartenbau oder andere Tätigkeiten, die Feuchtigkeit erzeugen, der aber durch wirkungsvollen Gebäude- und Dachentwurf entgegengewirkt werden muß;

3. DESIGN CONSIDERATIONS

3.1 Local Traditions and Codes

As is evident from the previous section, technical or climatological considerations in designing roofs must give precedence to those of local social and communal requirements. These aspects are, however, too complex to deal with in sufficient depth on a global scale. But in order to show the extent and nature of the questions that arise, some of the important ones are discussed below.

3.1.1 Local Traditions

Much of the information required for the roof design is taken for granted. Most tradition oriented societies strongly resist change and their aim is merely to achieve the standards of the well built houses of the area. However, since traditions have lost their continuity (on account of mixture of cultures, changed economic structures, political influences and the like), the functions of roofs and the ways they can be built are so numerous, that only a thorough consideration and exact definition of the various requirements can guarantee a satisfactory roof design.

Functions of the Roof

a. Is the roof, partly or as a whole, meant to be a temporary or permanent structure?

Temporary roof structures could be necessary in the case of sun shades, openings (for access, light, air or release of smoke) and temporary or portable buildings.

b. What is the roof intended to provide shelter for: people, livestock or goods?
What activities are expected to take place under the roof?

Examples of activities that may be influenced by the roof construction are:

- living patterns involving, for instance, sleeping, reading, talking, playing, listening to music, receiving guests, nursing the sick, praying, which are activities requiring thermal comfort as well as optical and acoustic privacy;
- work, such as handicrafts, small-scale industry, i.e. manual as well as nonmanual labour, all of which require sufficient light and thermal comfort;
- cooking, with or without open fires, calling for good ventilation and openings in the roof or chimney;
- bathing, washing, horticulture or other activities creating moist conditions, which must be remedied by efficient building and roof design;
- storage of goods, whether edible or not, normally requiring cool, dark and dry conditions;

- Lagern von Gütern, ob eßbar oder nicht, erfordert normalerweise kühle, dunkle und trockene Bedingungen;
- Tierhaltung, wofür Luft und Licht besonders wichtig sind.

Nichtbeachtung einer dieser Aktivitäten mit der Begründung, daß sie verboten sei, oder weil die Menschen zur Änderung ihrer Gewohnheiten angehalten werden sollen, würde wahrscheinlich negative Konsequenzen haben, wenn zum Beispiel Aktivitäten unter dem Dach wegen übermäßiger Aufheizung unmöglich werden, offene Feuer unter brennbaren Dächern angezündet werden oder gelagerte Nahrung durch tropfendes Kondenswasser verdorben wird.

c. Für welche Zwecke — außer der Schutzfunktion — wird das Dach sonst noch genutzt?

Beispiele für mögliche Nutzung sind:

- Zugang zum Haus (wie in den pueblos von Neu-Mexiko),
- Schlafen bei Nacht (wie in den meisten trocken-heißen Zonen),
- Umleitung von Wind für Ventilation (wie in vielen Ländern des Mittleren Ostens),
- Einsammeln von Regenwasser,
- Speicherung von Wasser, Nahrung und anderen Dingen,
- Trocknen von Nahrungsmitteln,
- Getreideworfeln,
- Gartenarbeit,
- Installation von Solardestilliergeräten oder Solarwarmwasserbereitern,
- oder einfach Repräsentation (je nach Hierarchischem Status des Bewohners).

d. Für welche Lebensspanne sollte ein Dach entworfen werden?

Dies hängt im allgemeinen von der Lebenserwartung des restlichen Gebäudes und der Einstellung des Bewohners zu Instandhaltung und Reparaturen ab, sowie von seiner Geschicklichkeit. Sehr oft hängt es auch vom Alter des Bewohners ab, besonders dort, wo es Brauch ist, das Haus nach seinem Tod abzureißen.

e. Welche religiösen und sozialen Aspekte beeinflussen Dachentwürfe?

Kosmische Orientierung kann mancherorts eine der baulichen Voraussetzungen sein (ein rundes Haus kann nicht orientiert werden), während anderswo dimensionale Erfordernisse berücksichtigt werden müssen (z.B. große Familien oder selbst ganze Dorfgemeinden — wie in Ozeanien — leben unter einem Dach) ebenso wie Einstellungen zu Formen, Materialien und Farben (z.B. ist der Kreis die perfekte Form für die Hottentotten, in Zentralamerika werden Asbestzementdächer rot gestrichen, um die herkömmlichen roten Ziegel nachzuahmen). In gewissen Kulturen stehen die Größen der Dachbalken und des Daches im entsprechenden Verhältnis zu ihrer Funktion als Statussymbol, während in anderen der Dekoration der Wände und Eingangstüren größere Bedeutung beigemessen wird.

- livestock keeping, for which air and light are especially important.

Disregard of any of these activities on the grounds that it is prohibited or that the people should alter their habits, would most likely have negative consequences, when, for example, activities under the roof become impossible due to overheating, open fires are lit under inflammable roofs or stored food is ruined by dripping water due to condensation.

c. Besides providing shelter, to what uses will the roof itself be put?

Examples of possible uses are:

- access to the house (as in pueblos of New Mexico),
- sleeping at nights (as in most hot arid regions),
- catching wind for ventilation (as in many countries of the Middle East),
- collection of rainwater,
- storage of water, food or other items,
- drying food,
- winnowing grain,
- gardening,
- installation of solar stills or solar water heaters,
- or just representation (in accordance with the heirachial status of the dweller).

d. For what life expectancy should the roof be designed?

This normally depends on the life expectancy of the rest of the building and the attitude of the dwellers towards maintenance and repair, as well as their skills. Quite often it also depends on the age of the dweller, especially in places where it is customary to demolish the house after his or her death.

e. What religious or social aspects are associated with local roof designs?

There may be a necessity for cosmic orientation (a round house cannot be oriented), while consideration must be given to dimensional requirements (e.g. large families or even entire village communities — as in Oceania — live under one roof) and to attitudes towards shapes, materials and colours (e.g. for the Hottentots the circle is the perfect form, in Central America asbestos cement roofs are coloured red to copy the traditional clay tiles). In certain cultures the sizes of roof beams and roofs are related to their function as a status symbol, while in others more importance is given to the decoration of walls and entrance doors.

3.1.2 Bauvorschriften

In allen älteren Kulturen war Tradition der hauptsächliche Regulator für Entwurf und Konstruktion von Häusern. Das Errichten von Gebäuden verlangte wenig Fachkenntnisse, konnte schnell erlernt und von den Bewohnern selbst ausgeführt werden. Heute jedoch ist die Tradition als Regulator in den wenigsten Gesellschaften noch vorhanden. Amos Rapoport gibt hierfür drei Gründe:

- die steigende Anzahl von Bautypen, wovon viele zu kompliziert sind, um sie in traditioneller Weise zu bauen,
- Verlust gemeinsamer Werte und Weltanschauungen,
- und die Tatsache, daß diese Gesellschaften Originalität belohnen.

Der resultierende Mangel an Kopperation erfordert die Einführung von Gesetzen, Regeln und ähnlichen Einschränkungen, die in Art und Umfang von Ort zu Ort verschieden sind, ebenso wie die Durchsetzung dieser Maßnahmen.

Entwurfskriterien für Dächer, wie sie von örtlichen Behörden vorgeschrieben werden, beziehen sich beispielsweise auf:

- Form, Neigung und Dimensionen, welche mit der Umgebung harmonieren müssen,
- Dachrinnen, die verboten sind, um das Ansammeln von Schmutz und stehendem Wasser zu verhindern,
- Gebrauch von brennbaren Materialien und Abstände von Gebäuden, um die Feuergefahr auf einem Minimum zu halten.

3.2 Klimatische Anforderungen

Die Tropen, welche als die Zone zwischen den 20° Isothermen definiert sind, bestehen aus einer Anzahl von Klimata, je nach Lage (Entfernung von großen Wassermassen, Entfernung vom Äquator, Höhenlage), Topographie, Geologie, Vegetation und ähnlichen Faktoren. Die Kompliziertheit der klimatischen Einflüsse auf Bauwerke erlaubt keine detaillierte Diskussion in diesem Zusammenhang, zumal dieses Thema in anderen Publikationen ausreichend behandelt wurde. Da Klimata in den Tropen in zwei Hauptgruppen geteilt werden können, nämlich solche, die überwiegend feucht und solche, die überwiegend trocken sind, wird es ferner ausreichen, die Entwurfserfordernisse dieser beiden Gruppen zusammenzufassen, ohne dabei zu vergessen, daß dies nur allgemeine Richtlinien sein können. Modifikationen der genannten Entwurfsprinzipien werden für die meisten Situationen nötig sein, da Mischklimata eher die Regel sind.

3.2.1 Dächer für feuchtwarmes Klima

Klimamerkmale

Temperatur : Durchschnittliches Maximum um 27° bis 32°C, durchschnittliches Minimum um 20° bis 27°C. Geringe tägliche und jährliche Temperaturvariationen in konstant feuchtwarmen Zonen, bei ausgeprägten jahreszeitlichen Unterschieden, jedoch zunehmend.

3.1.2 Building Codes

In all older cultures tradition was the major regulator in the design and construction of houses. The erection of buildings required few skills, were easy to grasp and could be carried out by the dwellers themselves. Today, however, tradition as a regulator has disappeared in most societies. Amos Rapoport gives three reasons for this:

- the increasing number of building types, many of which are too complex to build in traditional fashion,
- loss of common shared values and images of the world,
- and the fact that these societies put a premium on originality.

The resulting lack of cooperation necessitates the introduction of codes, regulations and similar restrictions, the nature and extent of which vary from place to place, just as much as their enforcement policies do.

Examples of criteria for roof designs as prescribed by the local authorities, may refer to:

- shape, slope and dimensions, which must harmonize with the surroundings,
- gutters, which are prohibited to prevent accumulation of dirt and standing water,
- use of inflammable materials and spacing of structures, with a view to minimizing fire risks.

3.2 Climatic Requirements

The tropics, which are defined as the area between the 20° isotherms, comprise a variety of climates, depending on location (distance from large water masses, distance from Equator, altitude), topography, geology, vegetation and similar factors. The complexity of climatological influences on building constructions forbid a detailed discussion in this context, as the subject has been amply dealt with elsewhere. Furthermore, since climates in the tropics can be divided into two major groups, namely those that are predominantly humid and those predominantly dry, it will suffice to summarize the design requirements of these two groups, keeping in mind that these can only be basic guidelines. Modifications of the given design principles will be necessary for most situations, since composite climates are more common.

3.2.1 Roofs for Warm Humid Climates

Characteristics of Climate

Temperature : Mean maximum about 27° to 32°C, mean minimum about 20° to 27°C. Little diurnal and annual temperature variations in consistently warm humid regions, increasing as seasonal changes become more distinct.

Feuchtigkeit : Relative Feuchtigkeit zwischen 55 und 100%, aber meistens über 75%, Dampfdruck liegt zwischen 2000 und 3000 N/m^2. Schwere Wolkendecke und Feuchtigkeitsgehalt der Atmosphäre dienen als Filter für direkte Sonneneinstrahlung.

Niederschlag : Kann zu jeder Zeit vorkommen oder jahreszeitlich im Mischklima. Jährliche Regenmenge 2000 bis 5000 mm, aber weniger als 2000 mm in Mischklimata.

Wind : Hauptsächlich niedrige Geschwindigkeiten, nur eine oder zwei Hauptrichtungen, häufig windstille Perioden. Monsunwinde meistens stark und beständig.

Vegetation : Reichlich, schnellwachsend durch häufigen Regenfall, hohen Grundwasserspiegel und warme Bedingungen. In gemischtem Klima viel weniger Vegetation, mit schnellem Wachstum nur während der Regenzeit.

Besonderheiten : Ständige Gefahr von Schimmel- und Algenwuchs, Rost und Fäule. Große Insektenplage und entsprechende Gefahr für organische Baumaterialien. Dichte Wolkendecke und Luftfeuchtigkeit verursachen schmerzhafte Blendung. In gemischtem Klima verursachen jahreszeitliche Veränderungen der relativen Feuchtigkeit Schwächung von Baumaterial, Kondensationsprobleme, Gefahr von Bodenerosion während des Monsuns, Staub- und Sandstürme während der Trockenzeit.

Allgemeine Entwurfsprinzipien

Orientierung : Bestimmt durch zwei primäre Anforderungen:
1) Einfangen von maximaler Luftbewegung
2) Minimale Sonneneinstrahlung auf Wände (erreicht durch Ausrichtung der Gebäudelängsachse in Ost-West-Richtung). Orientierung für Luftbewegung sollte Vorrang haben, da Sonnenstrahlen leicht durch Beschattungsvorrichtungen abgehalten werden können.

Abstände : Weite Abstände für maximale Luftzirkulation.

Grundriß : Gebäude in Windrichtung ein Raum tief für maximale Querlüftung. Häuser mit Innenhof für gemischtes Klima geeignet.

Öffnungen : Groß, 40 - 80% der Wandoberfläche, geschützt vor Sonne und Regen. Kleinere Öffnungen in gemischtem Klima.

Wände : Leicht, mit geringer Wärmekapazität, geschützt vor Sonne und Regen. In gemischtem Klima problematisch, wo kältere Jahreszeiten höhere Wärmekapazitäten erfordern.

Oberflächen : Maximale Reflexion.

Humidity : Relative humidity between 55 and 100%, but generally above 75%. Vapour pressures lie in the region of 2000 - 3000 N/m^2. Heavy cloud cover and vapour content of the atmosphere act as filter to direct solar radiation.

Precipitation : May occur any time of the year or seasonally in composite climates. Annual rainfall 2000 to 5000 mm, but less than 2000 mm in composite climates.

Wind : Generally low velocities, only one or two dominant directions, frequent calm periods. Monsoon winds usually strong and steady.

Vegetation : Abundant, growing quickly due to frequent rains, high subsoil water tables and warm conditions. In composite climates far less vegetation, with rapid growth only during rainy seasons.

Special Features : Constant risk of mould and algal growth, rusting and rotting. Insects constitute large nuisance factor and hazard to organic building materials. Dense clouds and atmospheric vapour cause painful sky glare. In composite climates, seasonal changes in relative humidity cause weakening of building materials, condensation problems occur, risk of soil erosion during monsoons, dust and sand storms in dry seasons.

General Design Principles

Orientation : Determined by two prime requirements:
1) to catch maximum air movement,
2) to minimise exposure of walls to solar radiation (achieved by placing building lengthwise in east-west direction). Orientation for air movement should have priority, since solar radiation is easily eliminated by shading devices.

Spacing : Wide for maximum unobstructed air circulation.

Plan : Rooms single banked in the direction of prevailing wind for maximum cross-ventilation. Courtyard buildings suitable for composite climates.

Openings : Large, 40 - 80% of wall surface, protected against sun and rain. Smaller openings in composite climates.

Walls : Light with low heat capacity, protected from sun and rain. Problems in composite climates, where colder seasons call for high heat capacity.

Surfaces : Maximum reflectivity.

Dachentwurf

Gestalt : - Geneigt für schnellen Wasserablauf, Neigungswinkel mit der Wasserdurchlässigkeit der Dachhaut zunehmend.

- Traufe weit überhängend, um Regenwasserabfluß in ausreichender Entfernung auch vom unteren Wandbereich zu gewährleisten und um Wände und Öffnungen zu beschatten.
- Vermeidung von waagerechten Dachkehlen und internen Dachrinnen, in denen sich Schmutz und Wasser ansammeln können.
- In Misch- und Hochlandklimata mit warmen, trockenen Jahreszeiten gut entwässerte flache Dächer zum Schlafen unter freiem Himmel und für andere Aktivitäten eventuell erwünscht.

Konstruktion : - Leicht, mit niedriger Wärmekapazität (sowohl tragende Teile als auch Dachhaut), um Wärmeentwicklung zu verhindern, welche nicht über Nacht abgegeben werden kann, da kein Temperaturrückgang.

- Luftraum zwischen Dachschichten zur Verminderung von Wärmeübertragung ins Innere, könnte aber Kondensationsprobleme hervorrufen, wenn die unteren Schichten undurchlässig sind und der Luftraum erheblich unter die Innentemperatur sinkt.
- Öffnungen unterhalb des Daches oder abgehängter Decken notwendig, um angestaute Wärme abzuführen.
- Ventilationsöffnungen und Dachhohlräume gegen Eindringen von Vögeln, Nagetieren und größeren Insekten abgesichert (z.B. durch Maschendraht), jedoch Vorsicht geboten, um Luftdurchzug nicht zu beeinträchtigen.
- Sorgfältige Wasserabdichtung aller Dachanschlüsse sowie Maßnahmen für Schallabsorption, um Lecken und unerträgliche Geräusche während tropischer Regenfälle zu verhindern.
- Bewegungsfugen an Bauwerken mit mehr als 25 m Länge, um Wärme-, Feuchtigkeits- und Setzungsbewegungen zu erlauben.
- Reflektierende Oberflächen reduzieren Wärmelast und Wärmebewegungen.
- Im Misch- und Hochlandklima schattenspendende Teile von Dächern abnehmbar, um die Sonne während der kalten Jahreszeit durchzulassen.
- Ausreichende Festigkeit, um das Gewicht der Bewohner, die auf dem Dach schlafen, zu tragen.

Materialien : - Keine idealen Materialien, da Anforderungen zu vielfältig, um von einem einzigen Material erfüllt zu werden, daher Kompromisse erforderlich.

Roof Design

Form : - Sloped for rapid run-off of rainwater, angle of slope increasing with permeability of roofing material.

- Wide overhanging eaves to throw rainwater well away from base of walls and provide shading of walls and openings.
- Avoidance of horizontal valleys and internal gutters, in which dirt and water can accumulate.
- In composite or upland climates with warm dry seasons, flat roofs with good drainage possibly desirable for outdoor sleeping and other activities.

Construction : - Lightweight, low thermal capacity structures (both supporting structures and covering) to avoid heat build up which cannot be dissipated at night, since there is no temperature drop.

- Provision of air space between roof layers can minimize heat transmission to interior considerably, but may create condensation problems, if lower layer is impermeable and air space cools well below temperature of interior.
- Openings below roof or suspended ceiling necessary to discharge accumulated heat.
- Ventilation openings and roof cavities protected against birds, rodents and large insects by means of screens (e.g. wire mesh), taking care not to hamper air flow substantially.
- Careful waterproofing of all roof junctions as well as measures for sound absorption to avoid leakage and unbearable noise during tropical downpours.
- Movement joints on buildings exceeding 25 m length to permit thermal, moisture and deflection movements.
- Reflective surfaces to reduce heat load and thermal movements.
- In composite and upland climates, parts of roofs functioning as sun shades made removable to facilitate exposure to sun during cold seasons.
- Sufficient strength to support weight of occupants using roof for sleeping.

Materials : - No ideal material exists, since requirements are too diverse to be fulfilled by a single material, hence compromises are necessary.

- Primary requirements for roofing materials: low thermal capacity; resistance to rain penetration, yet permeable enough to absorb moisture (e.g. water vapour, condensation) and release it when air is drier; resistance to fungus, insects, rodents and ultraviolet

- Hauptsächliche Erfordernisse für Dachmaterialien: niedrige Wärmekapazität, jedoch durchlässig genug, um Feuchtigkeit aufzunehmen (z.B. Wasserdampf, Kondensation) und sie wieder freizugeben, wenn die Luft trockener ist; Resistenz gegen Pilzbefall, Insekten, Nagetiere und ultraviolette Strahlen; reflektierend; widerstandsfähig gegen Einschlag (Hagel, fallende Kokosnüsse und Steine, usw.); unempfindlich gegen Temperatur- und Feuchtigkeitsschwankungen; frei von Gerüchen und Dämpfen.
- Gebrauch von Dämmstoffen, um Sonnenwärmedurchgang abzuhalten, immer noch fraglich. Hauptargument dagegen: Beeinträchtigung der Wärmeabgabe des Daches während der Nacht, dadurch Unbehaglichkeit der Bewohner und Bildung von Kondenswasser an der Unterseite der Isolierung durch Temperaturunterschiede auf beiden Seiten.
- Wirksamer Wärmeschutz durch Beschattung und richtige Anwendung von reflektierenden Materialien (z.B. Aluminiumfolie auf der Oberseite von abgehängten Decken).
- Feuchtigkeitssperren nicht geeignet, da Wasserdampf nicht entweichen kann und Kondensation verursacht.

3.2.2 Dächer für trockenheißes Klima

Klimamerkmale

Temperatur : Durchschnittliches Maximum 43° bis 49°C während warmer Jahreszeit, 27° bis 32°C während kalter Jahreszeit, und entsprechendes durchschnittliches Minimum von 24° bis 30° und 10° bis 18°C. Große tägliche und jährliche Temperaturschwankungen, aber tiefere Temperaturen und geringere Schwankung in Küstengebieten.

Feuchtigkeit : Sehr niedrige relative Feuchtigkeit, von 10 bis 55% schwankend und bis 90% in Küstennähe steigend; entsprechender Dampfdruck zwischen 500 und 2000 N/m^2.

Niederschlag : Jahresmenge niedrig, meistens weniger als 250 mm, mit unregelmäßigen Schauern über das ganze Jahr. In manchen Gebieten mehrere Jahre kein Regen.

Wind : Heiße Winde, die Sand und Staub tragen, örtlich auftretend, oft als Wirbelwinde. Richtung der Küstenwinde: Meer zu Land während des Tages, Land zu Meer während der Nacht.

Vegetation : Spärlich, trotz fruchtbaren Bodens, durch Regenmangel und niedrigen Grundwasserspiegel.

Besonderheiten : Fehlen von Wolken erlaubt intensive direkte Sonneneinstrahlung während des Tages und schnelle Wärmeabgabe nach Sonnenuntergang. Intensive Blendung und Hitze, hervorgerufen durch Sonnen-

radiation; reflectivity; resistance to impact (hail, dropping coconuts, falling stones, etc.); resistance to temperature and moisture fluctuations; freedom from odours and fumes.

- Use of insulating materials to intercept solar heat penetration still disputable. Main argument against them: interference of cooling action of roof during nights, causing discomfort for occupants and inducing condensation on underside of insulation, due to temperature difference on either side.
- Elimination of heat more effective by shading and proper use of reflective materials (e.g. aluminium foil on upper surface of suspended ceiling).
- Waterproofing membranes unsuitable, since water vapour cannot escape and causes condensation.

3.2.2 Roofs for Hot Dry Climates

Characteristics of Climate

Temperature : Mean maximum in hot season 43° to 49°C, in cold season 27° to 32°C, and corresponding mean minimum 24° to 30° C and 10° to 18° C. Large diurnal and annual temperature variations, but lower temperatures and less variations in coastal regions.

Humidity : Very low relative humidity varying from 10 to 55% increasing to 90% near the coast, corresponding vapour pressure ranging between 500 and 2000 N/m^2.

Precipitation : Low annual total, usually less than 250 mm, with irregular showers throughout the year. No rain in some region for several years.

Wind : Hot winds, carrying sand and dust, occurring locally, often as whirlwinds. Direction of coastal winds: sea to land during the day, land to sea during the night.

Vegetation : Sparse, in spite of fertile soil, due to lack of rain and low subsoil water table.

Special Features : Absence of clouds permits intense, direct solar radiation during the day and rapid dissipation of accumulated heat after sunset. Intense glare and heat caused by reflection of sunlight on light coloured, dry ground. Additional structural loads and abrasion of materials

Fig. 3.2
Traditional design for hot-dry climate (Algeria).

QUELLE/SOURCE:
Bauwelt 23/1976
"Wüstenstadt im M'Zab"

Luft, die damit in Kontakt kommt, abkühlt und zum Innenhof hin fällt, somit Kühlung angrenzender Räume;
2) Leichtes Einsammeln von Regenwasser, auch Verbesserung des Innenraumklimas.

- Windschaufeln, Türme mit Öffnungen zur Hauptrichtung des Windes zur Ableitung höher vorkommender Brisen in das Gebäude.

Konstruktion : - Vorwiegend schwere Konstruktionen mit hoher Wärmekapazität (wie für Wände), aber nicht für Erdbebenzonen geeignet.

- Zweischalige, leichte Dächer mit ausreichendem Hohlraum, um heiße Luft entweichen zu lassen.

- Äußere Schicht des Doppeldaches vorzugsweise mit Wärme-Isolierung, obere Flächen beider Schichten reflektierend.

- Für äußere Bereiche luftdurchlässige Dächer mit niedriger Wärmekapazität für Beschattung, jedoch ohne heiße aufsteigende Luft zurückzuhalten.

- In wasserreichen Gebieten Nutzung von Verdunstungskühlung durch Wasserflächen oder Sprühanlage auf dem Dach. Nachteile: Entstehung von Moskitobrutplätzen im Wasser, hohe Kosten für Sprühvorrichtungen.

- Geringe Gefahr von Schwitzwasserbildung, keine Dampfsperren nötig.

- Konstruktion ausreichend stark, um Gewicht der Bewohner auf dem Dach zu tragen.

- In Zonen mit extremen Temperaturschwankungen Bewegungsfugen alle 25 m erforderlich, die vorzugsweise ganze Teile des Gebäudes voneinander trennen. Reduzierte Wärmebewegungen durch Reflexion der Sonnenstrahlung und Beschattung.

Materialien : - Entweder Materialien mit hoher Wärmekapazität sowie äußere Isolierungsschicht, um die Wärmelast auf einem Minimum zu halten,

- oder zwei durch Luft getrennte Schichten niedriger Wärmekapazität, wobei die äußere oder beide aus Wärme-Isolierung bestehen.

- Wegen intensiver Sonneneinstrahlung höchstmögliche Reflexion der äußeren Oberflächen aller Schichten.

- Mit Rücksicht auf Dauerhaftigkeit sollte bedacht werden:
1) intensive Sonnenbestrahlung, gefolgt von schneller Abkühlung, macht Materialien spröde;
2) fliegender Sand und Staub verursacht Abrieb und Trübung der reflektierenden Oberflächen.

2) rainwater can be collected more easily, also improving indoor climate.

- Wind catchers, towers with openings facing main direction of wind, to redirect higher level breezes into building.

Construction : - Generally heavy, high thermal capacity structures (as for walls), but unsafe in earthquake zones.

- Double layered lightweight roofs with sufficient air space to dissipate hot air.

- Outer layer of double roof preferably with insulating material, upper surfaces of both layers reflective.

- For outdoor areas, permeable screen covers of low thermal capacity to give shade but allow rising hot air to escape.

- Where water is plentiful, pools of water or roof sprays provide cooling by evaporation. Disadvantage: risk of mosquito breeding in pools, high cost for spraying devices.

- Little risk of condensation, no vapour barriers required.

- Sufficient strength of structure to support weight of occupants frequenting roof.

- In regions with extreme temperature fluctuations, movement joints required every 25 m, preferably separating complete sections of buildings. Reduction of thermal movement by reflection of radiation and shading.

Materials : - Either high thermal capacity materials with external layer of insulation to minimize heat load,

- or two layers with low thermal capacity, and outer or both layers of heat resisting materials.

- Because of intense solar radiation, maximum possible reflectivity of outer surfaces of all layers.

- Considerations of durability should take into account:
1) intense solar radiation followed by rapid cooling, causing embrittlement of materials,
2) windblown sand and dust causing abrasion and dulling of reflective surfaces.

reflexion auf hellem, trockenem Boden. Zusätzliche Traglast und Abrieb von Materialien durch Staub und Sand. Schnelle Temperaturwechsel verursachen Schwächung und Zerfall von Materialien. Salzhaltige Luft beschleunigt Korrosion in Küstengebieten.

Allgemeine Entwurfsprinzipien

Orientierung : Bestimmt durch zwei primäre Anforderungen:
1) Ausschließen von heißer Luft, Sand und Staub
2) Reduzierung der Sonneneinstrahlung auf Außenflächen (erreicht durch Ausrichtung der größten Gebäudeflächen nach Norden oder Süden).

Abstände : Kompakte Anordnung der Gebäude, vorzugsweise mit Ost- und West-Wänden nahe beieinander, zur gegenseitigen Beschattung. Vermeidung von langen, geraden Straßen, um Durchzug von heißen Sandstürmen zu verhindern.

Grundriß : Nach innen gerichtet, mit der kleinstmöglichen Sonnenaussetzung. Kleine Innenhöfe (Breite weniger als Höhe) mit Wasser und Pflanzen zur Kühlung des Innenbereichs.

Öffnungen : Klein, 20 - 40% der Wandflächen, dicht unterhalb der Decke, gut beschattet. Idealerweise während des Tages geschlossen und während der Nacht geöffnet, obwohl aus Gründen der Intimität und Sicherheit schwierig durchzuführen.

Wände : Schwer, mit hoher Wärmekapazität und Phasenverschiebung von 9 - 12 Stunden, um Wärmedurchgang ins Innere bis zu den kühlen Stunden vor der Dämmerung zu verzögern und zur Erhaltung kühler Bedingungen im Inneren während Sonnenscheinperioden.

Oberflächen : Maximal reflektierend; glatte Oberflächen, um Ansammeln von Sand und Staub zu verhindern.

Dachentwurf

Gestalt : - Meistens flach, da Regenentwässerung kein Haupterfordernis ist, auch um Schlafen und andere Aktivitäten auf dem Dach zu ermöglichen.

- Gewölbe- und kuppelförmige Dächer sind auch häufig in heißen trockenen Klimata: gerundete Oberflächen verteilen Einstrahlung der hochstehenden Sonne, da Dachfläche größer als die Grundfläche, dadurch Reduzierung der Oberflächentemperaturen und Erleichterung der nächtlichen Rückstrahlung der Wärme.

- Dächer von Innenhofhäusern nach innen geneigt:
1) bei gut entworfenen und erhaltenen Dächern (gute Reflexion) nächtliche Abkühlung unter die umgebende Temperatur, so daß

due to dust and sand. Rapid temperature changes cause weakening and failure of building materials. Salt laden air in coastal areas accelerates corrosion.

General Design Principles

Orientation : Determined by two prime requirements:
1) to exclude hot air, sand and dust
2) to minimise exposure to solar radiation (achieved by facing larger dimensions of building towards north or south).

Spacing : Compact alignment of buildings, preferably placing east and west walls close together for mutual shading. Avoidance of long straight roads to check passage of hot sand storms.

Plan : Introverted, with smallest possible exposure to sun. Provision of small courtyards (width less than height) with water and plants for cool interiors.

Openings : Small, 20 - 40% of wall surface, placed close to ceiling, well shaded. Ideally, closed during day and opened at night, though difficult to implement for reasons of privacy and security.

Walls : Heavy, with high thermal capacity, and time-lag of 9 to 12 hours, to delay emission of heat to interior until cold pre dawn hours, and to retain cool conditions within during period of sunshine.

Surfaces : Maximum reflectivity, smooth surfaces to prevent collection of sand and dust.

Roof Design

Form : - Usually flat, since rainwater run-off is no major requirement, also to facilitate sleeping and other activities on roof.

- Vault and dome shaped roofs also common in hot dry climates: curved surface area, being considerably larger than base, distributes radiation of high sun, thus lowering surface temperatures and facilitating nocturnal reradiation.

- Roofs of courtyard houses sloping inwards:
1) well designed and maintained roofs (good reflection) cool below ambient temperature at night, so that air in contact with it cools and drops towards courtyard, cooling adjoining rooms;

Abb. 3.3
Traditionelle Bauweise für Hochlandklima (Guatemala).

Fig. 3.3
Traditional design for highland climate (Guatemala).

3.3 Schutz gegen Gefahren

Die Gefahren und deren jeweilige Schutzmaßnahmen in diesem Teil sind nur solche, die in Verbindung mit Dachkonstruktionen stehen. Es muß betont werden, daß sie generell im Zusammenhang mit der Konstruktion des übrigen Gebäudes gesehen werden müssen, wie stellenweise, wo erforderlich, darauf hingewiesen wird. Da sich die nachfolgend besprochenen Gefahren nicht auf bestimmte Klimazonen beziehen, werden diese nicht ausdrücklich erwähnt.

3.3.1 Biologische Schädlinge

Diese sind Insekten (Termiten, Bohrkäfer, Fliegen, Moskitos, usw.), Tiere (Ratten, Fledermäuse, Vögel, Schlangen, usw.) und Pilze.

Probleme

Auf Dächern nistende oder brütende Insekten können Gesundheitsrisiken (krankheittragende Moskitos und Fliegen) oder einfach eine Belästigung für die Bewohner des Gebäudes bedeuten. Gewisse Insekten (Termiten, Bohrkäfer) können organische Baumaterialien schwächen oder zerstören.

Ähnlich könnten Tiere, die sich in Hohlräumen verstecken, Gesundheitsprobleme oder Störung der Bewohner verursachen.

Durch Feuchtigkeit entstehende Pilze bilden unansehnliche Flecken auf fertigen Oberflächen, zerstören jedoch selten die Baustoffe selbst. Sie sind ein Zeichen von übermäßiger Feuchtigkeit, was unhygienische Bedingungen, schnellen Zerfall von organischen Baumaterialien und Korrosion von Metallen hervorruft.

3.3 Protection against Hazards

The hazards and the respective protective measures referred to in this section are only those associated with roof constructions. It must be stressed that they generally have to be dealt with in conjunction with the rest of the building construction, as is mentioned wherever necessary.
Since the hazards discussed below are not limited to any particular climatic regions, they are not specifically mentioned in the following.

3.3.1 Biological Agents

These include insects (termites, borer beetles, flies, mosquitos, etc.), animals (rats, bats, birds, snakes, etc.) and fungi.

Problems

Insects nesting or breeding on roofs can be a health hazard (disease carrying mosquitos and flies) or simply a nuisance to the occupants of the building. Certain insects (termites, borer beetles) can weaken or destroy organic building materials.

Similarly, animals lurking in roof cavities may create health problems or disturbances to occupants.

Fungi developing in moist conditions form unsightly patches on finished surfaces, but are seldom destructive to building materials. They are a sign of excess moisture, which can cause unsanitary conditions, rapid decay of organic building elements and corrosion of metals.

Abb. 3.4 Schädlingssichere Bambuskonstruktion (links: falsche, rechts richtige Methode)

Fig. 3.4 Vermin-proof bamboo construction (left: wrong, right: correst method)

QUELLE/SOURCE: United Nations "The Use of Bamboo and Reeds in Building Construction" (1972)

Schutzmaßnahmen

In bezug auf Insekten und Tiere:

- Vermeidung von Materialien, die Schädlinge anziehen, und von unkontrollierbaren Hohlräumen, in denen sie nisten können;
- Vermeidung von Löchern oder Vertiefungen, in welchen sich Wasser und Schmutz ansammeln können, worin Moskitos, Fliegen, Küchenschaben und ähnliches brüten können;
- Anbringung von Termitenblechen am Fundament des Gebäudes und Vergiftung der Erde, um unterirdischen Termiten den Zugang zum Dach zu verwehren;
- Behandlung von organischen Materialien mit Insektiziden, wenn natürlich widerstandsfähiges Material nicht verfügbar;
  (Bemerkung: Obwohl allgemein üblich, besteht hier die Gefahr, daß das Insektizid von Regen oder Kondenswasser weggespült wird, dadurch Herabsetzung der Termitenresistenz und Entstehung einer Gesundheitsgefährdung).
- Anbringung von Maschendraht, um Ungeziefer fernzuhalten;
- Gebrauch von Materialien, die innerhalb des Daches Temperaturen entstehen lassen, die zu hoch sind, um Ungeziefer bestehen zu lassen;
  (Bemerkung: Unerwünschte Hitze könnte dadurch im Gebäudeinneren entstehen);
- Vermeidung von dichter Vegetation in der Nähe des Gebäudes, um Schädlingen keinen leichten Zugang zu ermöglichen.

Protective Measures

With respect to insects and animals:

- avoidance of materials that attract pests and have uncontrollable cavities for them to nest in;
- avoidance of pockets or depressions in which water and dirt can accumulate providing breeding places for mosquitos, flies, cockroaches, etc.;
- provision of termite shields at base of building and poisoning of soil to prevent subterranean termites from gaining access to roof;
- poisoning of organic materials for termite resistance, if naturally resistant material is not available;
  (Note: though this is a common practise, there is a risk of insecticide being washed out by rain or condensation, thus reducing the termite resistance and constituting a health hazard)
- provision of wire mesh at openings, to keep out pests;
- use of materials creating temperatures within roof, too high for pests to exist;
  (Note: the consequence could be undesirable heating of building interior)
- avoidance of dense vegetation close to building to reduce access links for pests.

Abb. 3.5 (a, b) Methoden zur Behandlung von frischem Bambus mit chemischen Lösungen

a. Boucherie-Verfahren, wobei Bambussaft durch Schutzlösung ersetzt wird. Dauer: 5 Tage, aber mit Druckbehandlung nur wenige Stunden.

b. Tauchmethode, wobei chemische Lösung vom Stamm aufgesaugt wird aufgrund der Feuchtigkeitsabgabe von den Blättern.

Es kann eine große Anzahl anderer Schutzbehandlungen angewendet werden, wovon eine einfache, wirksame Methode darin besteht, die geschnittenen Rohre zur Beseitigung der Feuchtigkeit zu räuchern.

Fig. 3.5 (a, b) Methods of treating fresh bamboo with preservative solutions

a. Boucherie process, by which the sap of the bamboo is substituted by the preservative. Duration: 5 days, but with pressure treatment only few hours.

b. Dipping method, by which chemicals are drawn up the stem due to transpiration of moisture from leaves. Duration: 1 to 2 weeks.

A great number of other protective treatments may be employed, a simple and effective method being smoking of cut culms to remove all moisture.

In bezug auf Pilzbildung:

- Verhinderung von Feuchtigkeitsansammlungen durch Ventilation und Entwässerung;
- Gebrauch von natürlich widerstandsfähigen Materialien (z.B. gut abgelagerte Hölzer, Zementfarbe, Kalkanstrich, nicht ölgebundene Leimfarbe), Fungiziden; geringe Verwendung von organischen Materialien.

Im allgemeinen:

- Aufrechterhaltung sauberer Bedingungen, um keine Nährböden für Ungeziefer und Pilze entstehen zu lassen;
- Ermöglichung von Zugang zu allen Teilen des Daches für regelmäßige Inspektionen.

3.3.2 Wind und Regen

Die Faktoren, die eine Gefahr für Gesundheit oder Leben der Bewohner darstellen und die für die Gebäudekonstruktionen schädlich sein können, sind örtliche Gewitterstürme, Sandstürme, Tornados, tropische Wirbelstürme, Wolkenbrüche und Hagel.

Probleme

Starke Winde (Tornados, tropische Wirbelstürme) verursachen, je nach Dachneigung, Überhang und Durchlässigkeit, positiven oder negativen Luftdruck (Sog) auf verschiedene Teile des Daches, wodurch Bruchschäden entstehen oder Dachelemente vollkommen abgerissen werden. Umherfliegende Gegenstände können Gebäude schädigen und Leben gefährden.

Fliegender Sand, der sich auf Dächern ansammelt, vergrößert die Traglast und gefährdet schwache Bauwerke. Er verursacht auch den Abrieb von Materialien, Trübung von Oberflächen und großes Unbehagen für die Bewohner.

Schwere Regen in den Tropen können
- Dachelemente lockern und loslösen,
- Bruchschäden und das Durchdringen von Wasser verursachen,
- Oberflächenanstriche, Insektizide und Fungizide fortspülen,
- auf nicht schallabsorbierenden Dächern erhebliche Geräuschbelästigung verursachen,
- Überschwemmungen von Gebäuden verursachen, wobei mit steigendem Wasser Luft unter dem Dach eingeschlossen wird und dadurch einen starken Auftrieb gegen das Dach und seine Befestigungen an den Wänden zur Folge hat. Zusätzlich entstehen hohe Verkehrslasten auf dem Dach durch Menschen, die Zuflucht vor der Überschwemmung suchen.

Abb. 3.6 (a, b) Wirkung der Dachneigung bei Winddruck: maximaler Sog bei etwa 10° Neigung

Fig. 3.6 (a, b) Effect of roof slopes on wind pressure: maximum suction at about 10° pitch

With respect to fungi:

- avoidance of moisture concentrations by means of ventilation and drainage;
- use of naturally resistant materials (e.g. well-seasoned timbers, cement paint, lime wash, non-oil-bound distempers) and fungicides, minimum use of organic materials.

In general:

- maintenance of clean conditions to provide no feeding grounds for pests and fungi;
- provision of access to all parts of roof for periodic inspection.

3.3.2 Wind and Rain

The factors constituting a hazard to the health or life of the occupants and which may be detrimental to building construction are local thunderstorms, sand storms, tornadoes, tropical cyclones, torrential downpours and hail.

Problems

Strong winds (tornadoes, tropical cyclones) exert positive and negative pressures (suction) on different parts of roofs, depending on their slopes, overhangs and permeability, causing partial breakage or complete displacement of elements. Flying objects can then damage other buildings and endanger lives.

Wind blown sand accumulates on flat roofs increasing loads and endangering weak structures. They also cause abrasion of materials, dulling of surfaces and great discomfort to dwellers.

Heavy rains in the tropics can
- loosen and dislocate roof elements,
- cause breakage and penetration of water,
- wash off surface coatings, insecticides and fungicides,
- create extreme noise disturbance on roofs which do not absorb sound,
- cause inundation of buildings, trapping air below the roof as water rises, thus imposing strong upthrust on the roof and its fastenings to walls. In addition high live loads are imposed on the roof by people seeking refuge from the floods.

Hagelstürme mit großen Hagelsteinen können Dachelemente und andere Gebäudeteile beschädigen oder zerbrechen.

Gewitterstürme sind oft von gewaltigen Blitzeinschlägen begleitet, welche hochliegende Teile, die Metall oder Feuchtigkeit enthalten, treffen, und Verwüstung verursachen.

Schutzmaßnahmen

In bezug auf starke Winde:

- Vermeidung von flachen oder flach geneigten Dächern mit weniger als 20° (etwa 1 : 3),
- Vermeidung von leichten Dächern und breiten Überhängen,
- Gebrauch von dauerhaften Materialien (fähig, fliegenden Gegenständen Widerstand zu leisten), am Unterbau stark befestigt,
- unnachgiebige und starke Verankerung zum tragenden Bauwerk,
- Querverstrebungen, um Verwindungen und Bruchschäden der Dachelemente auf ein Minimum zu halten,

abgesehen von einer Anzahl anderer Schutzmaßnahmen für den Rest des Gebäudes.

In bezug auf vom Wind getragenen Sand:

- Vermeidung von Taschen und Oberflächen, in welchen sich Sand und Staub ansammeln können,
- Gebrauch von abriebfesten Materialien.

a. b.

Abb. 3.7 (a, b)

a. Druckverhältnis bei Überflutung des Gebäudes: starker Auftrieb gegen das Dach, verursacht durch Lufteinschluß zwischen Wasser und Dach.

b. Einplanung von Lüftungsöffnungen so hoch wie möglich, um Luft entweichen zu lassen.

Fig. 3.7 (a, b)

a. Effect of inundation of building: strong upthrust on roof due to air trapped between water and roof.

b. Provision of ventilation openings as high as possible to allow air to escape.

Hail storms with large hailstones can seriously damage or break roofing elements and other building parts.

Thunderstorms are often accompanied by violent air to ground lightening, which strikes high lying elements containing metals or moisture, causing devastation.

Protective Measures

With respect to strong winds:

- avoidance of flat or low pitched roofs with slopes less than 20° (about 1 : 3);
- avoidance of light roofs and wide overhangs;
- use of durable materials (capable of withstanding impacts of flying objects) firmly attached to substructure;
- rigid and strong anchorage of roof to supporting structure;
- cross-bracing to minimize distortion and breakage of roof members;

apart from a number of other protective measures involving the rest of the building.

With respect to wind blown sand:
- avoidance of pockets and surfaces on which sand and dust may accumulate;
- use of abrasion resistant materials.

Abb. 3.8

Erdbebenwiderstand mittels Stahlbetonringbalken, der mit dem Fundament Stahlbeton-Verbindung hat.

Fig. 3.8

Earthquake resistance by means of reinforced concrete ring beam which has strong reinforced connections to the foundations.

In bezug auf schwere Regenfälle (zusätzlich zu den Erfordernissen für Windwiderstand):

- hoch widerstandsfähige Wasserabdichtung (von Verbindungsstellen) und Oberflächenanstrich,
- minimaler Gebrauch von Insektiziden und Fungiziden,
- Verwendung von schalldämpfenden, wasserabweisenden Materialien,
- Öffnungen an den oberen Enden des Daches, um eingeschlossene Luft während Überschwemmungen freizulassen,
- starke Dachkonstruktionen, ausreichend, um Lasten heraufsteigender Flüchtlinge während Überschwemmungen tragen zu können,
- Aufbewahrung von empfindlichen Materialien im Dachboden (z.B. Beladen der Untergurte der Dachbinder), um sie vor Wasserschäden zu schützen und den aufwärts wirkenden Kräften entgegenzuwirken.

In bezug auf Hagelstürme:

- Gebrauch von Materialien, die Hagelsteineinschlägen widerstehen,
- ausreichende Dachüberstände, um Fenster zu schützen.

In bezug auf Blitzeinschlag beziehen sich Schutzmaßnahmen hauptsächlich auf Standortwahl (keine hohe Lage relativ zur Umgebung), Aufstellen von teuren Blitzableitern und Feuerschutz. Metall und feuchtigkeitaufnehmende Dächer in blitzgefährdeten Zonen erfordern daher fachmännische Beratung über Aufstellen von Ableitungsmasten und Erdung.

Im allgemeinen müssen alle Schutzmaßnahmen zur Verhinderung nachteiliger Folgen von Wirbelstürmen und Regen Möglichkeiten für Inspektion und Instandhaltung des Bauwerkes und der Befestigungspunkte einbeziehen. Fachgerechte Ausführung ist jedoch die wichtigste Schutzmaßnahme.

3.3.3 Erdbeben und Feuer

Diese beiden Gefahren können zusammen behandelt werden, da nach schweren Erdbeben in den meisten Fällen Feuer ausbricht.

Probleme

Schwere Dächer oder lose Teile, auch verschiedene Aufbauten wie Wasserbehälter, Schornsteine und Brüstungen, können abgeschüttelt werden oder zusammenbrechen und damit Unfälle herbeiführen.

Zusammenfallende Wände ziehen daraufliegende Dächer mit sich.

Schäden an Schornsteinen und Versorgungsleitungen verursachen generell das Ausbrechen von Feuer.

Schutzmaßnahmen

Widerstand gegen Zusammenbruch erfordert:

- entweder monolithische Dächer oder solche aus starken, flexiblen Elementen, die

With respect to heavy rains (in addition to the requirements for wind resistance):

- highly resistant waterproofing (of joints) and surface coating;
- minimum use of insecticides and fungicides;
- use of sound absorbing, water repellant materials;
- openings in top ends of roofs to allow trapped air to escape during floods,
- strong roof constructions, sufficient to carry live loads of refugees during floods,
- storage of vulnarable material in roof space (e.g. by loading bottom chords of roof trusses), thus protecting them from water damage and helping to counter-act upward loads.

With respect to hail storms:

- use of materials resistant to impact of falling hailstones;
- sufficient overhangs to protect windows below.

With respect to lightning, protective measures mainly involve siting (no high situation relative to surroundings), installation of expensive lightning conducting systems and fire protection. Metal or moisture absorbing roofs in lightning prone situations, therefore, require expert advice on erection of conductor masts and earthing.

In general, all protective measures to counteract adverse effects of wind storms and rain must incarporate means for inspection and maintenance of structure and joints. However, the prime protective measure is good workmanship.

3.3.3 Earthquakes and Fire

These two hazards can be seen together as fires nearly always occur after severe earthquakes.

Problems

Heavy roofs or loose elements, also various appendages, like water tanks, chimneys and parapets, are likely to be shaken off or collapse, causing casualties.

Wall failures cause roofs, resting on them, to fall down.

Breakage of chimneys and mains supply lines generally causes outbreak of fire.

Protective Measures

Resistance to collapse calls for:

- either monolithic roofs or ones comprising strong, flexible members, firmly tied

fest an das tragende Bauwerk gebunden sind,

- Dächer, die sicher an einem durchgehenden Ringanker befestigt sind, welcher wiederum durch Stahlbetonrahmen zusammengehalten wird,
- oder, alternativ, Dächer auf freistehenden Stützen, von den Wänden statisch getrennt, so daß im Falle des Versagens der Wände das Dach nicht einstürzen würde,
- kompakte symmetrische Formen in Grundriß und Aufriß, um eine möglichst gleichmäßige Lastverteilung zu erreichen,
- statische Trennung von Dachteilen, um bei unsymmetrischen Gebäuden unabhängige, kompakte Formen zu bilden,
  (Bemerkung: diese Trennung muß bis zum Fundament heruntergeführt werden, um wirksam zu sein),
- Vermeidung von großen Spannweiten,
- Vermeidung von überstehenden Teilen wie Brüstungen, Wasserbehälter, nicht-monolithische Schornsteine, sowie von losen Abdeckungen, die leicht herabfallen können,
- Vermeidung schwerer Materialien auf schwachen Stützen,
- Vermeidung von spröden Materialien oder von solchen, die nur oberflächlich verbunden sind, z.B. gemauerte Kuppeln oder Gewölbe,
- Schutzmaßnahmen, die das Schwächen von Dachelementen durch biologische Schädlinge verhindern.

Verhinderung von Feuer verlangt:

- Vermeidung von leicht entzündbaren Materialien in der Nähe von Schornsteinen und Strom- sowie Gasleitungen,
- nicht-brennbare Dachdeckung (z.B. Asbestzement) über Materialien, die weniger feuerbeständig sind,
- ausreichende Abstände zu Nachbardächern in der Hauptwindrichtung,
- Vermeidung von Hohlräumen in Dächern, die, als Rauchzug wirkend, das Feuer schnell verbreiten lassen,
  (Bemerkung: dies erfordert Kompromisse, wenn belüftete Dachhohlräume zur Verbesserung des Innenraumklimas erforderlich sind),
- chemische Behandlung von Materialien, wobei Imprägnierung besser ist als Oberflächenbehandlung, aber Dächer, die dem Regen ausgesetzt sind, erfordern regelmäßige Wiederholung dieser Behandlung,
- Vermeidung von leicht entzündbaren Materialien in der Nähe von potentiellen Feuerquellen.

Wie schon vorher erwähnt, können alle Schutzmaßnahmen für Dächer nur dann wirksam sein, wenn auch für den übrigen Teil des Gebäudes die entsprechenden Entwurfsmaßnahmen getroffen werden.

down to supporting structure,

- roofs securely fixed to a continuously reinforced ring beam on top of walls, which itself is held together by a reinforced framework,
- or alternatively, roofs fixed to independent supports, structurally separated from walls, which, in the event of failure, would not cause the roof also to collapse,
- compact, symmetrical shapes, in plan and elevation, to obtain as uniform a stress distribution as possible,
- structural separation of roof sections, to form independent compact shapes on unsymmetrical buildings,
  (Note: this separation must be carried through down to the foundations to be effective)
- avoidance of large spans,
- avoidance of projecting elements, such as parapets, water tanks, non-monolithic chimneys, and loose roof coverings that tend to fall down,
- avoidance of heavy material on weak supports,
- avoidance of brittle materials, or ones that only have surface bonding, e.g. masonry domes or vaults,
- protective measures that resist weakening of roof members by biological agents.

Resistance to fire calls for:

- avoidance of combustible materials near chimneys and power and gas lines,
- non-combustible cladding (e.g. asbestos cement) on materials less resistant to fire,
- sufficient separation of neighbouring roofs in direction of prevailing winds,
- avoidance of cavities or air spaces in roofs, which can act as flues spreading fire rapidly,
  (Note: this necessitates a compromise if ventilated roof space is required to improve indoor climate),
- chemical treatment of materials, impregnation being better than brush treatment, but roofs exposed to rain require regular renewal of treatment,
- avoidance of storage of combustible materials close to potential sources of fire.

As mentioned before, all protective measures for roofs can only be effective if corresponding steps are taken in designing the rest of the building.

3.4 Materialwahl

Es gibt kein universales Rezept für Bedachungsmaterialien; jedes hat seine Vor- und Nachteile, je nach Anwendungsmethode, Klima- und Umwelteinflüssen, Verfügbarkeit und ähnlichen Faktoren. Die Materialwahl für Bedachungen ist gewöhnlich ein Kompromiß, da die Anforderungen an eine ideale Dachkonstruktion sehr vielfältig sind, können sie selten von einem einzigen oder einer Kombination von Materialien erfüllt werden.

Der Zweck dieses Abschnittes ist es deshalb, allgemeine und spezifische Information über herkömmliche billige Bedachungsmaterialien zu geben, Information, die nötig ist, um deren geeignete Verwendung für eine gegebene Situation zu beurteilen.

3.4.1 Anorganische Materialien

Stein

Anwendung :
- Steinmetzgewölbe und Kuppeln
- Plattenbelag für Flachdächer
- Kiesbelag (z.B. weiße Steinsplitter als Sonnenschutz für Asphaltdächer)
- Zuschlagstoff für Betondächer

Vorteile :
- in den meisten Zonen ausreichend vorhanden
- gute Wärmeeigenschaften in trockenheißen Zonen
- keine Feuchtigkeitsbewegung, nur sehr gering bei Kalk- und Sandstein
- keine biologischen Risiken, wenn Oberflächen sauber sind

Nachteile :
- Wärmebewegungen können Risse verursachen
- CO_2 in Regenwasser greift Kalkstein und kalkhaltigen Sandstein an
- in Regenwasser gelöster Schwefel bildet wasserlösliches Sulfat in Verbindung mit Kalkstein — Hautbildungen und Erosion sind mögliche Folgen
- Angriffe von bestimmten Salzen und salzhaltiger Luft führt zur Ausblühung und zu Oberflächen-Ausbrüchen
- schwer, gefährlich (besonders während Erdbeben), wenn nicht gut gebaut

3.4 Choice of Materials

There are no universal recipes for roofing materials; each one has its advantages and disadvantages, depending on the method of application, climatic and environmental influences, availability and other similar factors. The choice of the roofing fabric is usually a compromise, since an ideal roof construction must fulfil a wide range of requirements, which rarely are satisfied by a single one or even combination of materials.

The purpose of this section is, therefore, to give general and specific information on common low-cost roofing materials, information that is required to be able to judge their oppropriateness for a given situation.

3.4.1 Inorganic Materials

Stone

Applications:
- Stone masonry vaults and domes
- Slabs as surface finish for flat roofs
- Gravel convering (eg. white stone chips as solar protection of bitumen roofing)
- Aggregate in concrete roofs

Advantages:
- In most regions sufficient supplies
- Good thermal performance in hot-dry areas
- No moisture movement, only very minor for limestone and sandstone
- No biological risks, if surfaces are clean

Disadvantages:
- Thermal movement can cause cracking
- CO_2 in rainwater attacks limestones and calcerous sandstones
- Sulphur dissolved in rainwater forms water-soluble sulphates with limestones — skin formation and erosion can occur
- Attack by certain salts and sea spray leads to efflorescence and spalling
- Heavy, dangerous (especially during earthquakes) if not well constructed.

Abb. 3.9 (a, b, c) Traditionelle Erddachkonstruktionen
Fig. 3.9 (a, b, c) Traditional soil roof constructions

QUELLE/SOURCE: P. Bardou, V. Arzoumanian, "archi de terre" (1978)

Abhilfe : - Erhaltung sauberer Oberflächen; Regenwäsche reduziert Hautbildung durch Entfernung von löslichen Sulfaten

Erde

Anwendung : - Lehmziegel oder stabilisierte Erdblöcke für Kuppeln oder Gewölbekonstruktionen. Herkömmliche Stabilisierungsmittel:
a. Bewehrung — organische oder Mineralfaser
b. Bindemittel — Zement, Kalk (meistens billiger, ausreichende Stärke)
- Erdschicht über Holz, Bambus, Schilfunterbau
- gebrannte Tonziegel und Platten als Dachdeckung

Vorteile : - hohe Wärmespeicherungskapazität, gut für trocken-heiße Klimazonen
- fast keine Kosten, kein Transport
- keine biologischen Risiken, wenn Erde frei von organischen Substanzen ist

Nachteile : - obwohl reichlich vorhanden, Erden örtlich nicht immer geeignet, da Erdzusammensetzungen und -qualitäten sehr verschieden sind
- gebrannte Tonziegel nicht immer einheitlich, wenn örtlich hergestellt. Verschiebungen während Erdbeben, starke Schäden durch herabfallende Ziegel
- schwere Erddächer nicht für erdbebengefährdete Zonen geeignet
- schwache Erdmischungen können durch Wärme und Feuchtigkeitsbewegungen Risse hervorrufen und sich im Regen auflösen

Remedies: - Maintenance of clean surfaces; rain washing reduces skin formation by the removal of soluble sulphates.

Soil

Applications: - Adobe or stabilized soil blocks as domes or vault structures. Common stabilizers:
a. reinforcement — organic or mineral fibres
b. binders — cement, lime (usually cheaper, sufficient strength)
- Soil layer over timber, bamboo, reed substructures
- Burnt clay bricks and tiles for roofing

Advantages: - High heat storage capacity, good for hot-dry climates
- Almost no cost, no transport
- No biological hazards, if soil is free from organic matter

Disadvantages: - Though abundantly available, local soils may not always be appropriate, since soil compositions and qualitities differ greatly.
- Burnt clay tiles not always uniform if locally made. Displacement during earthquakes, causing severe damage
- Heavy soil roofs unsuitable for earthquake areas
- Weak soil mixes quickly develop cracks with thermal and moisture movement, and disintegrate in heavy rains.

c.

Abhilfe : - einfache Untersuchungsmethoden für die verschiedenen Erdetypen erforderlich
- Erdmischung so trocken wie die Verarbeitung zuläßt
- schützende Anstriche in regelmäßigen Abständen auftragen, um Erosion zu verhindern
- Zusatz von Mitteln zur Erhöhung der Wasserresistenz (z.B. Asphalt, Bitumen, Bitumenemulsion, Zement, und andere natürliche oder industriell hergestellte Produkte).

Remedies: - Simple tests for various soil types required
- Soil mixtures as dry as practical
- Protective coatings applied at regular time intervals to prevent erosion
- Addition of waterproofing agents (eg. asphalt, bitumen, cutback, cement and other natural or industrially produced materials).

Abb. 3.10 Tonziegeldach in China (ähnlich wie Mönch- und Nonnen-Deckung)
Fig. 3.10 Clay tile roof in China (similar to Spanish type)

Abb. 3.11 Tonziegeldach in Brasilien
Fig. 3.11 Clay tile roof in Brazil

Metalle

Anwendung : - am häufigsten verzinktes Wellblech, weniger häufig Aluminiumblech. Beide Typen haben normalerweise größeres Ansehen als andere Materialien (andere Metalle und Legierungen sind zu teuer und nicht ausreichend vorhanden)
- Anschlußblech und Befestigungsmaterialien (z.B. Nägel)
- Bewehrungseisen für Stahlbetondächer
- Stahl und Aluminiumrahmen
- Netze zum Schutz von Öffnungen
- Dachrinnen

Metals

Applications: - Most common are corrugated galvanized iron sheets, less common aluminium sheets. Both types normally have greater prestige value than other materials. (Other metals and alloys too expensive and not sufficiently available)
- Flashings and fastening materials (eg. nails)
- Reinforcement in concrete roofs
- Steel or aluminium frames
- Netting for protection of openings
- Gutters

Abb. 3.12 Verzinkte Wellblechdächer in Somalia — am wenigsten geeigneter Dachtyp für die Region

Fig. 3.12 Corrugated galvanized iron roofs in Somalia — most inappropriate roof type for the region

Vorteile : - leichter Transport (niedriges Gewicht, keine Bruchschäden)
- große Spannweiten möglich, einfache Stützkonstruktion
- große Stärke und Flexibilität (gutes Erdbebenverhalten)
- hoher Widerstand gegen Aufschläge
- Widerstand gegen alle biologischen Schädlinge
- Wasserundurchlässigkeit
- einfache und schnelle Installation
- generell keine Ablehnung durch Bevölkerung

Nachteile : - wegen Mangel an Wärme-Isolierung übermäßig hohe Innentemperaturen während des Tages, sehr tiefe Temperaturen während der Nacht
- nächtliche Abkühlung verursacht Kondensation auf der Unterseite des Daches, dadurch Beeinträchtigung des Wohnkomforts
- Lärmbelästigung bei schweren Regenfällen
- Korrosion von Platten und Bewehrung bei Feuchtigkeit (in feuchtwarmen und Küstengebieten, bei Kondensation, usw.)
- Korrosion durch Elektrolyse, bei Kontakt zwischen verschiedenartigen Metallen
- Neigung der dünnen Bleche, an genagelten oder geschraubten Stellen unter starkem negativem Druck abzureißen (besonders wenn nur kleine oder keine Unterlegscheiben benutzt werden)
- in tropischen Wirbelstürmen: Zerstörungen durch umherfliegende Blech die abgerissen wurden
- Abrieb durch windgeblasenen Sand
- schlechtes Feuerverhalten
- teurer Transport durch zentralisierte Produktion, oft hoher Devisenanteil

Abhilfe : - Hitze und Kondensation: Vermeidung von Blechdächern in Gebieten mit intensiver Sonnenstrahlung und schnellen Temperaturänderungen. Zweischalige Dächer mit belüftetem Zwischenraum (untere Schicht wasserabsorbierend). Reflektierende Außenfläche.
- Korrosion: keine Verwendung unter feuchten Bedingungen. Geeignete Schutzanstriche periodisch erneuern. Regenwasser kann durch Herauswaschen schädlicher Salze Korrosion hemmen. Im Falle ungleicher Metalle Verwendung von nichtmetallischen Unterlegscheiben. Keine Kontakte zwischen Aluminium und Beton oder Mörtel (alkalische Korrosionsgefahr)
- Geräusch: kürzere Spannweiten und Bitumenanstrich auf der Unterseite. Außerdem sorgfältige Detaillierung der Befestigungspunkte und Anbringung von Dämmschichten oder abgehängten Decken
- Auftrieb: stärkere Bleche, bessere Verbindungen

Abb. 3.13 Demonstrationsbau in Togo: Abgehängte Bambusdecke unter dem Wellblechdach, mit belüftetem Dachzwischenraum

Advantages: - Easy transports (low weight, no breakage)
- Wide spans possible, simple supporting structure
- High strength and flexibility (good earthquake performance)
- High resistance to impact
- Resistance to all biological hazards
- Impermeable to water
- Easy and rapid installation
- Generally high acceptability

Disadvantages: - Due to lack of thermal insulation, intolerably high indoor temperatures during daytime, very low temperatures at night
- Nocturnal cooling causes condensation on underside of roofs, affecting indoor comfort
- Problem of noise generated by heavy rains
- Corrosion of sheets and reinforcement in moist (hot humid and coastal areas, condensation, etc.) conditions
- Corrosion by electrolytic action due to contact of dissimilar metals
- Tendency of thin sheets to tear off at nailed or bolted points (particularly with small or no washers) under strong negative pressure
- In tropical windstorms: havoc caused by whirling sheets that have been ripped off
- Abrasion caused by wind blown sand
- Poor fire resistance
- Expensive transports due to centralized production, often high foreign currency component

Remedies: - Heat and condensation: Avoidance of sheet metal roofs in areas of intense solar radiation and rapid temperature changes. Double layer roofs with ventilated air space (absorptive lower layer). Reflective outer surface
- Corrosion: Avoidance of use in moist conditions. Suitable protective coatings periodically renewed. Rainwashing can retard corrosion by removing contaminating salts. In case of dissimilar metals, non-metallic washers. No contacts of aluminium with concrete or mortar (risk of alkaline corrosion)
- Noise: Shorter spans and coating of bitumen on underside. Also careful detailing of suspension points and application of insulating layers or suspended ceiling
- Uplift: Thicker gauged sheets, better connections.

Fig. 3.13 Demonstration structure in Togo: suspended bamboo ceiling under corrugated iron roof, creating ventilated roof space.

Zement-Produkte

Anwendung :
- Bindemittel für verschiedene organische und nicht-organische Materialien, z.B. Erdzement, Bimsbeton, Asbestzement (siehe nächsten Baustoff), Bauplatten aus zementgebundenen Naturfasern
- Beton, Stahlbeton, Leichtbeton für Dachplatten, Balken, Schalen, usw.
- Ferrozement (im wesentlichen dünne Betonschichten mit Bewehrung aus Hühnerdraht) für Schalenkonstruktionen in beliebigen Formen
- Isolier- oder Gefälleestrich

Vorteile :
- extrem hohe Festigkeit
- gutes Erdbeben- und Wirbelsturmverhalten bei Stahlbeton
- wasserdicht, bei guter Verarbeitung
- feuerhemmend
- widerstandsfähig gegen biologische Einwirkung, wenn sauber gehalten
- Materialien von höherem Ansehen

Nachteile :
- in den meisten Ländern zu teuer und Zementversorgung weit unter dem Bedarf. In einigen Ländern nur eine Zementfabrik, dadurch hohe Transportkosten
- unter feuchten Bedingungen Gefahr des zu frühen Abbindens von gelagertem Zement
- in trockenheißen Gebieten Gefahr der Rissebildung durch zu schnelle Austrocknung von frischem Beton
- Schrumpfungsrisse durch Temperaturschwankungen
- Betonschwächung durch salzhaltige Aggregate oder Wasser
- Rosten von nicht ausreichend bedecktem Bewehrungsstahl führt zu Dehnungsrissen
- zur Erlangung der Festigkeiten von teurem stahlbewehrtem Beton sind erforderliche Betonquerschnitte mit billigerer Bambusbewehrung zu groß
- im allgemeinen schwere Konstruktionen und gefährlich bei Erdbeben, wenn nicht richtig geplant und ausgeführt

Abhilfe :
- Vermeidung von zu schnellem Abbinden durch Befeuchtung des Betons während der Aushärtung
- Prüfung von Betonproben zur Qualitätskontrolle
- gute Kornverteilung der Aggregate, um übermäßige Schrumpfung zu vermeiden und größere Stärke zu geben
- Einplanung von Dehnfugen, wo erhebliche Wärmebewegungen zu erwarten sind
- sorgfältige Zementlagerung (vor Feuchtigkeit schützen)

Cement Products

Applications:
- Binder for several inorganic and organic materials, eg. soil-cement, pumice cement, asbestos-cement (see next material), cement bound vegetable fibre boards.
- Concrete, reinforced concrete, light-weight concrete for roof slabs, beams, shells, etc.
- Ferrocement (basically thin layered reinforced concrete with chicken wire mesh) for free form shell structures
- Insulating roof screeds

Advantages:
- Extremely high strengths
- Good earthquake and hurricane performance of reinforced concrete
- Waterproof, if well done
- Fire resistant
- Resistant to biological hazards, if kept clean
- Materials of higher prestige value

Disadvantages:
- In most countries expensive and insufficient supplies of cement. In some countries only one manufacturing plant, therefore high transport costs.
- In presence of moisture, risk of premature setting of cement.
- In hot dry conditions, risk of cracks due to rapid setting.
- Shrinkage cracking due to temperature fluctuations
- Weakening of concrete due to aggregates or water containing salts
- Rusting of steel reinforcement, not sufficiently covered, leading to expansion cracks
- To achieve similar strengths as expensive steel reinforcements, necessary cross-sections for cheaper bamboo reinforcements are too large
- Generally heavy constructions and dangerous in earthquakes, if not properly designed and executed

Remedies:
- Avoidance of rapid setting by moistening of concrete during curing
- Sample testing of concrete for quality control
- Good grading of aggregates to avoid excessive shrinkage and to give greater strength
- Design of expansion joints, where substantial thermal movement is expected
- Careful storage of cement (protection from moisture).

Abb. 3.14 Standard-Betondach in Tansania
Fig. 3.14 Standard concrete roofing in Tanzania

Abb. 3.15 Betonschalendach in Togo
Fig. 3.15 Concrete shell roof in Togo

Asbestzement

Anwendung :
- flache Platten, Schindeln
- Wellplatten
- trogförmige Elemente (z.B. Canaletas)
- Sonnenschutzvorrichtungen

Vorteile :
- leicht zu handhaben, geeignet für Selbsthilfe-Bauweisen
- feuerbeständig, wasserdicht
- Well- und Trogplatten: selbsttragend über große Spannweiten (kein Unterbau nötig)
- geringe Wärmebewegung
- bessere Wärme-Isolierung und weniger Geräusch bei Regen als mit Metallplatten

Nachteile :
- kontinuierliche Hydratation des Zements führt zu Längenzunahme
- unzureichender Widerstand gegen Einschlag (z.B. Schäden durch Hagelsteine)
- Schimmelbildung durch Ansammlung von Schmutz an den Fasern verursacht Erweichen und Verdunkeln der Oberfläche

Asbestos Cement

Applications:
- Flat sheets, shingles
- Corrugated sheets
- Trough shaped elements (eg. Canaletas)
- Sun screening

Advantages:
- Easy to handle, suitable for self-help construction
- Fire resistant, waterproof
- Corrugated and trough shapes: self-supporting over large spans (no substructure necessary)
- Low thermal movement
- Better heat insulating capacity and less noisy in heavy rain than metal sheets

Disadvantages:
- Continued hydration of cement causing length increase
- Insufficient resistance to impact (eg. damage by hailsones)
- Mould growth on fibre-held dirt, causing surface softening and darkening
- Warping and cracking promoted by combined carbonation and

- Verbiegen und Platzen, gefördert durch kombinierte Karbonation und Austrocknen
- Verringerung der Schlagbiegefestigkeit durch CO_2 in Gegenwart von kleinen Mengen H_2O
- Entfernen von Oberflächenschichten des hydratisierten Zements durch CO_2 oder durch die im Regenwasser aufgelösten Schwefelgase
- hohe Bruchverluste während des Transports

Abhilfe : - schützende Anstriche gegen Schimmelbildung
- Erhaltung von sauberen Oberflächen

hydration
- Decrease of impact strength by CO_2 in presence of small amounts of H_2O
- Removal of surface layers of hydrated cement by CO_2 or sulphur gases dissolved in rainwater
- High degree of breakage during transports

Remedies:
- Protective coating against mould growth
- Maintenance of clean surfaces

Abb. 3.16 Asbestzement-Trogplattendächer (canaletas) in El Salvador
Fig. 3.16 Asbestos cement channel roofing (canaletas) in El Salvador

3.4.2 Organische Materialien

Gräser, Palmen, pflanzliche Fasern

Anwendung : - Gräser:

a. herkömmliche Stroh- und Mattendächer
b. Strohbewehrung in Spanplatten, Erdzementmischungen, usw.
c. Strohpreßplatten (z.B. Stramit), industriell hergestellt mittels Hitze und Druck, ohne Bindemittel, aber mit Papier auf beiden Seiten
d. Schilf, gebündelt oder zu Platten zusammengebunden, oder gespalten und als Matten gewebt, für unterschiedliche Verwendung als Dachelemente
e. ganze Bambushalme für Tragkonstruktion, oder als Platten zusammengebunden
f. halbierter Bambus als Dachziegel und -rinnen
g. gespaltener Bambus als gewebte Platten oder Bewehrung für diverse Bauplatten.

- Palmen:

h. Blätter, unverarbeitet oder als Matten, für Dachdeckung
i. Stämme für tragende Bauteile

- Pflanzliche Fasern:

j. Seile
k. Faserplatten
l. Bewehrung für diverse Bauplatten

Vorteile : - meistens reichlich am Ort vorhanden, billig (oder kostenlos), schnell zu erneuernde Materialien. Können im Hinterhof angebaut werden.
- Traditionelle Verarbeitungstechniken (in den meisten Fällen), leicht verständlich und ausgeführt von Ortsansässigen
- Strohdächer, korrekt angewandt: gute Wärme- und akustische Eigenschaften und wasserdicht
- Schilf und Bambus: hohe Zugfestigkeit, gutes Gewicht/Festigkeit-Verhältnis, deshalb normalerweise gutes Verhalten bei Erdbeben und Wirbelsturm
- Strohpreßplatten: hohe dimensionale Stabilität, widerstandsfähig gegen Einschlag und Spaltung, nicht leicht entzündbar, (wenn trocken gehalten) widerstandsfähig gegen biologische Schädlinge, Verarbeitung wie Holzplatten
- generell gutes Erdbebenverhalten, aber gegen Wirbelstürme nur dann widerstandsfähig, wenn gut geplant und ausgeführt

Nachteile : - in den meisten Fällen niedrige Lebenserwartung, ungefähr 2 - 5 Jahre, doch durch gute Konstruktion und Instandhaltung kann längere Haltbarkeit erreicht werden
- biologische Risiken (Anziehung und Nisten von Insekten, Nage-

3.4.2 Organic Materials

Grasses, Palms, Fibrous Plants

Applications: - Grasses:

a. Traditional straw thatch and matting
b. Straw reinforcements in particle boards, soil cement mixes, etc.
c. Compressed straw slab (eg. Stramit), industrially produced by heat and pressure, without any binders, but paper on both sides
d. Reeds, bundled or tied together as boards or split and woven as mats, for various uses as roofing elements
e. Full bamboo culms as supporting structure, or tied together as boards.
f. Halved bamboo as roof tiles and gutters
g. Split bamboo as woven panels or reinforcement in composite roofing elements

- Palms:

h. Leaves as thatch or matting
i. Stems as structural members

- Fibrous Plants:

j. Ropes
k. Fibreboards
l. Reinforcement in composite roofing elements

Advantages: - Usually locally available abundant, cheap (or even no-cost), quickly renewable materials. Can be grown in backyard
- Traditional techniques (in most cases), easily comprehended and implemented by local people
- Straw thatch, properly applied: good thermal and acoustical properties and waterproofing
- Reeds and bamboo: high tensile strengths, good weight-strength ratio, hence usually good earthquake and hurricane performance
- Compressed straw slabs: high dimensional stability, resistance to impact and splitting, not easily ignitable, (if kept dry) resistance to biological hazards, handled like timber boards
- Generally good earthquake performance, but hurricane resistance only if well designed and constructed

Disadvantages: - In most cases low life expectancy, about 2 to 5 years, though with good constructions and maintenance greater durability achievable.
- Biological risks (attraction and nesting of insects, rodents, etc. and development of fungi and rot)
- Risk of fire, either originating underneath or spread through flaming or glowing fragments carried by wind

tieren, usw. und die Entwicklung von Pilzen und Fäulnis)
- Feuergefahr, entweder durch darunter entstehende Feuerquellen oder durch vom Wind getragene Flammen oder glühende Fragmente
- Tendenz, Feuchtigkeit aufzusaugen, infolgedessen Gewichtszunahme, beschleunigter Verfall und Entstehung unhygienischer Bedingungen
- Verformung und allmähliche Zerstörung durch ständig wechselnde Temperaturen und Feuchtigkeit
- nicht sehr beliebt aufgrund allgemeiner Ansicht, daß diese Materialien minderwertig sind und nur bei "Häusern armer Leute" gebraucht werden

Abhilfe :
- Imprägnierung der Materialien gegen biologische Schädlinge und Feuer, entweder durch Vorbehandlung oder durch Oberflächenauftragung (Vorsicht: diese sind teuer und werden leicht durch Regen fortgewaschen, wodurch die Umgebung und das von den Dächern gesammelte Trinkwasser verseucht werden. Ferner fördern Feuerschutzbehandlungen Schimmelbildung und somit schnellen Verfall)
- Reduzierung der Feuergefahr bei Strohdächern durch Auftragen einer Schicht stabilisierten Tons auf die Außenseite, um Entzünden durch fliegende, glühende Fragmente zu verhindern. Regel-

- Tendency to absorb moisture thus becoming heavy, accelerating deterioration and creating unsanitary conditions
- Deformation and gradual destruction due to constant fluctuations in temperature and humidity
- Low acceptance due to general view that these materials are inferior, used only for "poor peoples' houses"

Remedies:
- Impregnation of materials against biological hazards and fire, either by pretreatment or surface application. (Caution: These are costly, and easily washed out by rain, contaminating surroundings and drinking water collected from roof. Moreover fire resistant treatments may promote mould growth, leading to rapid decay).
- Reduction of fire risk on thatch roofs by application of thin coat of stabilized clay on exterior to prevent ignition by windborne fragments. Periodic renewal necessary.
- Reduction of rate of burning by restriction of air flow through thatch in event of fire, eg. by means of non-combustible material (asbestos cement sheets) attached to underside of roof.
- Maintenance of dry conditions within dwelling advantageous; development of smoke in interior said to prevent rot and nesting of insects.

3.17

3.18

mäßige Erneuerung nötig.

- Reduzierung der Flammenverbreitung, indem der Luftzug durch das Stroh verringert wird, z.B. durch Befestigung von nicht brennbaren Materialien (Asbestzementplatten) unterhalb des Daches.
- Aufrechterhaltung trockener Bedingungen innerhalb der Behausung von Vorteil; interne Rauchentwicklung verhindert Fäulnis und Insektennisten.

Fig. 3.22 Bamboo roof truss with details of joints.

Holz

Anwendung : - alle Teile des tragenden Bauwerks, wie Ringbalken, Sparren, Pfetten, Binder, Streben, First
- Dachverkleidungen, wie Sperrholz, Tischlerplatten, Spanplatten oder Schindeln

Vorteile : - hohe Zugfestigkeit und gutes Gewicht/Festigkeit-Verhältnis, dadurch gute Erdbeben- und Wirbelsturmbeständigkeit
- traditionelle Materialien, die traditionelle Techniken erfordern
- gute Feuerbeständigkeit der dickeren Bauelemente: äußere Schichten entwickeln verkohlte Schutzschicht
- gute Wärme-Isolierung, auch schallschluckend

Nachteile : - schwindende Reserven durch Raubbau und Export, dadurch hohe Kosten
- Mangel an langsam wachsenden Hölzern (härter, stärker und widerstandsfähiger gegen Termitenbefall)
- Wärme- und Feuchtigkeitsbewegungen: Schrumpfung (aber nur in der Breite), Verzerrung, Spaltung
- anfällig gegen biologische Schädlinge
- Feuergefahr für kleinere Holzbauteile
- Korrosion der Metallverbindungen oder Schrumpfung an Anschlußpunkten, was zum Versagen der Verbindungen führt

Timber

Applications: - All parts of supporting structure, such as ring beam, rafters, purlins, trusses, struts, ridge
- Roof finishes, such as plywood, coreboard, chipboard or shingles.

Advantages: - High tensile strengths and good weight-strength ration, hence also good earthquake and hurricane resistance.
- Traditional material involving traditional skills.
- Good fire resistance of thicker timber members: outer layer develop protective charred surface.
- Good thermal insulation, also sound absorption.

Disadvantages: - Diminishing supplies due to uncontrolled cutting and exports, hence high costs
- Shortage of slow grown timber (harder, stronger and more resistant to termite attack)
- Thermal and moisture movement: shrinkage (but only in width), twisting, splitting
- Susceptible to biological hazards
- Fire risk of timber members with smaller dimensions
- Corrosion of metal connectors, or shrinkage at points of connection leading to failure of joints

Abhilfe : - Anstreichen oder Behandeln mit verschiedenen Holzschutzölen (feuchtigkeitsgefährdete Holzteile: Behandlung der später nicht zu erreichenden Teile vor dem Zusammenbau)
- Holzteile, die nicht dem Regen ausgesetzt sind: in Salzwasser (Meerwasser) vorbehandeln, um Pilzbefall zu vermeiden und weniger Verzerrungen durch den hohen Feuchtigkeitsgehalt
- Verhinderung von Pilzbefall bei gut abgelagerten Hölzern mit Feuchtegehalt von weniger als 20 Gewichtsprozent
- Schützen von Dachanschlüssen, in die Wasser eindringen kann, mittels Metall- oder Plastikabdeckprofilen, aber keine luftdichte Befestigung
- Verbindungen, die Bewegungen aufnehmen können

Remedies: - Painting or treatment with various wood-preserving oils. (Timber likely to become damp: primed in future inaccessible parts before assembly)
- Timber parts not exposed to rain-washing: soaked in salt water (sea water) for prevention of fungal attack and less warping, due to higher moisture content.
- Prevention of fungal attack with well seasoned wood containing less than 20% by weight
- Protection of joints liable to trap moisture by means of metal or plastic flashing, but no air-tight fastening
- Joints designed to accomodate movement.

Bituminöse Produkte

Anwendung : - Dachpappe auf Holz- oder Betondächern
- Splittasphalt, geeignet für Dächer, die dem Fußverkehr ausgesetzt sind
- kalt aufgetragener Asphalt, meist emulsionbasiert, da gelöster Asphalt teuer und feuergefährlich ist
- Wellpappe, aus Abfallmaterialien hergestellt (weich zermahlen, imprägniert mit normalem Straßenasphalt, geschützt durch Mineralgranulat oder Farbe)

Bituminous Products

Applications: - Roofing felts laid on wood or concrete roofs
- Mastic asphalt, suitable for roofs subjected to foot traffic
- Cold applied bitumen, usually emulsion based, since solvent based bitumens are costly and constitute fire risk
- Corrugated roofing sheets made from waste materials (reduced to pulp, impregnated with common paving asphalt, protected with mineral granule or paint)

Vorteile : - Wellplatten: leicht, erfordern leichte Unterkonstruktion, nicht spröde, dadurch keine Transportschäden; keine Fachkräfte oder spezielle Werkzeuge erforderlich; kann direkt auf den Unterbau genagelt werden; wasserdicht; nicht wärmeleitend (Isolierungswert entspricht ungefähr einer 6 cm dicken Betonplatte)
- kalt aufgetragenes Bitumen: keine Fachkräfte nötig
- biologische Schädigung nicht sehr wahrscheinlich

Nachteile : - ultraviolette Strahlen verursachen Versprödeln, Rissebildung und das Entstehen wasserlöslicher Verbindungen
- Ausdehnung von eingeschlossener Luft oder Wasser führt zu Blasenbildung
- Hitze verursacht Erweichen und Fließen
- durch stehendes Wasser Entstehung von Haarrissen, Filzfasern können verrotten, Oberflächenschutzgranulat kann so vom Regen fortgewaschen werden
- Wasserlachen verursachen unterschiedliche Spannungen durch Verdampfungskühlung
- wiederholtes Nässen und Trocknen beeinflussen die visco-elastischen Eigenschaften
- starke Winde können Versprödung und Abreißen verursachen, Schutzgranulat wird fortgeblasen
- ungeeignet für Temperaturen über 44°C
- kaltes Bitumen begrenzt lagerfähig (schnell zu verbrauchen, innerhalb von drei Monaten; Verschiffungsprobleme)

Abhilfe : - ausreichender Schutz gegen Sonnenstrahlung durch reflektive Behandlung (z.B. Kalkanstrich, Aluminiumfarbe, hellfarbige Aggregatsplitter), eventuell auch Dachbeschattung
- ausreichende Dachneigung (mindestens 3%) und Entwässerung, um Wasserlachen zu verhindern
- Bewegungsfugen, die gegensätzliche Bewegungen zwischen Membrane und Unterkonstruktion ermöglichen
- Ankleben in Abständen, um Wasserdampfblasen zu vermeiden, aber bessere Aufklebung dort, wo Wirbelstürme vorkommen, die die Dachpappe lossaugen könnten
- Bewehrung der Dachpappe, vorzugsweise nicht organisch (z.B. Asbest oder Glasfaser); andere, wie Stoffilz, sind anfällig für biologische Schädigung
- Zusatz von Konservierungsmitteln, um Zerfall zu verhindern
- Kaltbitumen: gründliches Mischen vor Gebrauch, in dünnen Schichten auftragen (wenn kein Regen und nicht zu heiß)
- gute Facharbeit und regelmäßige Instandhaltung, d.h. Inspektion und regelmäßig alle paar Jahre neuer Bitumenanstrich

Advantages: - Corrugated sheets: light, requiring light substructure; not brittle, hence no transport breakage; no skilled labour or special fixing equipment; can be nailed to substructure directly; waterproof; non-conducting (insulation value corresponding to about 6 cm concrete slab)
- Cold applied bitumen: no skill required
- Attack by biological agents not very likely

Disadvantages: - Ultra-violet radiation causes embrittelement, cracking and formation of water soluble compounds
- Expansion of entrapped air or water gives blistering
- Heat couses softening and flow
- Standing water causes crazing, felt fibres may rot. Surface protective granules can thus be washed off by rain
- Standing puddles cause differential stresses due to evaporation cooling
- Repeated wetting and drying affects visco-elastic properties
- High winds can cause cracking and tearing, blowing off protective granules
- Unsuitable for temperatures exceeding 44°C
- Cold bitumen has limited storage life (quick use, within three months; shipment problems)

Remedies: - Adequate protection against solar radiation by reflective treatment (eg lime wash, aluminium paint, light-coloured aggregate chippings) possibly also roof-screening
- Sufficient roof inclination (minimum 3%) and drainage to avoid standing puddles
- Movement joints, allowing differential movements between membrane and substructure
- Adhesion at intervals to prevent blistering due to water vapour, but better adhesion where wind storms occur, which may suck off felt
- Reinforcements of roofing felts preferably inorganic (eg. asbestos or glass fibre). Others, like rag felt, are susceptible to attack by biological agents
- Addition of preservatives to prevent decay
- Cold bitumen: thorough mix before use, applied (when no rain and not too hot) in thin layers
- Good workmanship and regular maintenance, i.e. inspection and periodic coating of bitumen every few years.

Anstriche

Anwendung

- auf verzinktem Blech: Vorbehandlung — entfetten, "weißen Rost" entfernen, aufrauhen, korrosionsbeständiger Grundanstrich (z.B. zwei Anstriche mit Epoxidasphalt); Fertigfläche — ein oder zwei Anstriche mit Außenfarbe (z.B.Acrylharzemulsionsfarbe)
- auf Asbestzement, Beton, Mauerwerk: Vorbehandlung — Staub, Algen usw. abbürsten, Schutzschicht aus 1% Kupfer-Sulphat-Lösung gegen Algen; Grundierung — alkalibeständiger Anstrich; Fertigfläche — zwei Anstriche (z.B. Chlorkautschukfarbe, Kunststoffemulsionsfarbe, Zement- oder Kalkfarbe)
- auf Holz: Vorbehandlung — ablagern, abschmirgeln und säubern, Grundanstrich; Fertigfläche — Farben, die nicht die Poren schließen (Firnissen für Außenflächen nicht ratsam), Oberanstriche können Fungizide enthalten
- auf Bitumen: keine Vorbehandlung; Oberanstrich — Aluminiumpigment- oder bituminöse Aluminiumfarbe; Kalkanstrich auch möglich, aber weniger haltbar

Vorteile

- Schutz gegen Sonnenbestrahlung durch Reflexion
- Schutz gegen Wind und Regen durch Zusammenhalten loser Teilchen, Verschließen durchlässiger Materialien, korrosionsbeständig
- Schutz gegen biologische Schädigung durch den Gebrauch von Fungiziden und Insektiziden
- Verbesserung der äußeren Erscheinung und der hygienischen Bedingungen
- Verbesserung der Haltbarkeit

Nachteile

- plastikbasierte Farben müssen hauptsächlich von Industrieländern importiert werden (aber örtliche Herstellung nimmt zu)
- Farben werden durch Sonnenbestrahlung, Feuchtigkeit, windgetragenen Sand, atmosphärische Verunreinigungen, Schimmelbildung und Termitenbefall zerstört
- falsch aufgetragene Anstriche können zu beschleunigter Zerstörung der Substrate führen
- Kalkanstriche erfordern Erneuerung nach jeder Regenzeit

Abhilfe

- größte Wichtigkeit ist die Vorbereitung des Substrats, um maximale Haftfestigkeit des Oberanstrichs zu sichern
- Erhaltung von sauberen Oberflächen und periodische Erneuerung der Anstriche
- auf Substraten, die dazu neigen, Feuchtigkeit aufzusaugen, möglichst keine Verwendung undurchlässiger Farben; statt dessen Farben, die "atmen", z.B. Emulsions-, Kalk- oder Zementfarben

Paints

Applications:

- On galvanized iron: Treatment — degreasing and removal of "white rust", roughening, corrosion resistant primer (eg. two coats epoxy tar). Finish — one or two coats of exterior paint (eg. acrylic emulsion paint)
- On asbestos cement, concrete and masonry: Treatment — dust, algae, etc. brushed off, protective coating of 1% copper sulphate solution against algal growth. Primer — alkali resistant primer. Finish — two coats (eg. chlorinated rubber paint, plastic emulsion paint, cement paint or limewash).
- On timber: Treatment — seasoning, sand-papering and cleaning, primer. Finish — paints that do not seal pores (varnishing not advisable for exterior), finishes may incorporate fungicidal ingredients.
- On bitumen: No prior treatment. Finish — aluminium pigmented or bituminous aluminium paint. Also limewash possible, but less durable.

Advantages:

- Protection against solar radiation by reflection
- Protection against wind and rain by bonding loose particles, sealing permeable material, corrosion resistance
- Protection against biological hazards by use of fungicides and insecticides
- Improvement of appearance and sanitary conditions
- Improvement of durability

Disadvantages:

- Plastic based paints mainly imported from industrialized countries (but local production increasing)
- Deterioration of paints by solar radiation, moisture, wind-blown sand, atmospheric pollution, mould growth and even termite attack
- Wrongly applied paints may lead to quicker deterioration of substrates
- Limewash requires renewal after each rainy season

Remedies:

- Greatest importance given to preparatory treatment of substrate to ensure maximum adherence of finish
- Maintenance of clean surfaces and periodic renewal of coatings
- On substrates that tend to absorb moisture, avoidance of impervious coatings; instead paints that "breathe", eg. emulsion paints, lime or cement wash.

Kunststoffe

Anwendung :
- Feuchtigkeitsisolierung und Dampfsperren, z.B. Polyäthylen, Polyvinylchlorid (PVC), Butylkautschuk, Polyisobutylen
- Wärmedämmung durch Schaumstoffe (z.B. Polyurethan-Schaumplatten) und Verbundplatten
- begrenzter Gebrauch von Wellplatten, z.B. PVC und glasfaserverstärktes Polyester, wegen Verwitterungsproblemen
- monolithische Dächer, meist Doppelwölbungen oder Faltplattenanordnungen zur Aussteifung (z.B. glasfaserverstärktes Polyester)

Vorteile :
- große Auswahl an Formen, Farben und anderen physikalischen Eigenschaften; Nachahmung von traditionellen Produkten, um hiermit Verbraucherwiderstand gegen Unbekanntes zu überwinden
- leichtgewichtig, was Handhabung und Transport verbilligt und erleichtert; zusätzlicher Vorteil durch geringen Aufwand für Tragkonstruktion
- keine Korrosion, leicht sauberzuhalten
- keine Feuchtigkeitsbewegungen

Nachteile :
- Plastik verbreitet Flammen, entwickelt schädliche Dämpfe und dichten Rauch
- Mangel an Festigkeit, Tendenz sich allmählich zu verformen, selbst bei normalen Temperaturen, und schneller Verfall der mechanischen Eigenschaften bei höheren Temperaturen
- Verfall durch Ultraviolettstrahlung (immer noch unausreichende Information vorhanden über Kunststoffanwendung unter tropischen Bedingungen)
- große Wärmebewegungen im Gegensatz zu traditionellen Materialien
- hauptsächlich aus Industrieländern importiert, verhältnismäßig teuer
- die meisten Plastikarten, außer den harten Varianten, anfällig für Termitenbefall und Abrieb durch windgetragenen Sand

Abhilfe :
- möglichst keine Anwendung, wo Feuer entstehen kann
- Schutz gegen Hitzequellen
- Vermeidung von lang anhaltender mechanischer Belastung, welche zu Bruchschäden führen könnte
- weitgehende Abschirmung gegen Sonnenbestrahlung, falls kein hoch-widerstandsfähiges Material verwendbar
- Schutzmaßnahmen gegen Termiten und windgetragenen Sand

Plastics

Applications:
- Water proofing membranes and vapour barriers, eg. polyethylene, polyvinyl chloride (PVC), butyl rubber, polyisobutylene
- Thermal insulation with cellular plastics, eg. polyurethane foam slabs and sandwich panels
- Limited use of corrugated roofing sheets, eg. PVC and glass reinforced polyester, due to problems with weathering behaviour
- Monolithic roofs, usually employing double curvature or folded-plate arrangements for rigidity, eg. glass-fibre reinforced polyester.

Advantages:
- Capability to take on a wide variety of forms, colours and other physical properties. Imitation of traditional products, as a means of overcoming consumer resistance due to unfamiliarity
- Lightness in weight, making handling and transportation easier and cheaper. Additional advantage in reduction of supporting structure
- No corrosion, easily kept clean
- Not subject to moisture movements

Disadvantages:
- Ability of plastics to spread flame, develop noxious fumes and dense smoke
- Lack of rigidity, tendency to "creep", even at ambient temperatures, and rapid decline in mechanical properties at elevated temperatures
- Deterioration due to ultra-violet radiation (still insufficient data available on use of plastics in tropical conditions)
- Large thermal movement relative to most traditional materials
- Mainly imported from industrilaized countries, relatively high costs
- Most plastics, except hard varieties, susceptible to termite attack and abrasion by wind-borne sand.

Remedies:
- Avoidance of use, where fires are likely to occur
- Protection from heat sources
- Avoidance of prolonged mechanical stress, which could lead to breakage
- Minimum exposure to solar radiation, unless highly resistant materials are used
- Protective measures against termites and wind-borne sand.

3.4.3 Abfallmaterialien

Landwirtschaftliche Abfälle

Anwendung :
- Bewehrungsfasern für verschiedene Anwendungen (z.B. stabilisierte Erde und Beton) aus Bagasse, Kokosnußschalen, Bananenstengeln
- Füllstoffe für Spanplatten, Faserstoffplatten, usw. von Reisschalen, Kokosnußschalen, Holzrückständen
- leichtgewichtige Füllstoffe für Beton aus getrockneten Reisschalen, karbonisierten nicht-eßbaren Körnern
- pozzulanische Materialien aus Reisschalenasche
- wasserfeste Beschichtungen aus Bananenstengel (in ein wenig Wasser gekocht), flüssiges Harz aus Kaschunußschalen

Vorteile :
- extrem billige Rohstoffe
- Reduzierung der durch Anhäufung von Abfall geschaffenen Umweltprobleme

Nachteile :
- oft nicht ausreichend vorhanden, da viele Abfälle als billiges Heizmaterial benutzt werden, obwohl die Vorteile, sie in billiges Baumaterial umzuwandeln, viel größer sein könnten

Abhilfe :
- intensivere Forschung der technologischen Aspekte sowie Kosten/Nutzen-Analyse
- gesetzliche Maßnahmen für die Organisation der Abfallwiederverwertung

Industrieabfälle

Anwendung :
- Zuschlagstoffe für Beton aus Flugasche (befeuchtet, zu Kügelchen geformt und gesintert), Schaumhochofenschlacke (durch Zugabe von etwas Wasser zur schmelzflüssigen Schlacke)
- hydraulische Bindemittel aus Flugasche und "Surkhi" (pulverisierter Mauer- und Dachziegelausschuß, hauptsächlich in Indien verwendet)
- Mineralwolle (als Füllstoff für Bitumenpappe) aus Flugasche
- feuchtigkeitsisolierende Anstriche aus Schwefel

Vorteile :
- die gleichen wie für landwirtschaftliche Abfälle
- gut etablierte Technologien in vielen Ländern

Nachteile :
- nur bei Verwendung von Schwefel: Entwicklung von Giftstoffen und Gerüchen bei hoher Temperatur (50°C), Sprödigkeit und Schrumpfung während des Erhärtens, muß in flüssigem Zustand aufgetragen werden (Probleme des verfrühten Erhärtens), erfordert spezielle Werkzeuge
- verfrühtes Erhärten von Flugasche unter feuchten Bedingungen

Abhilfe :
- Erforschung neuer Techniken zur kostengünstigen Anwendung von Schwefel
- Lagerung von Flugasche mit der gleichen Sorgfalt wie von Zement.

3.4.3 Waste Materials

Agricultural Waste

Applications:
- Reinforcement fibres for various uses (eg. stabilized soil and concrete) from bagasse, coconut husks, banana stalks
- Fillers for particle board, fibreboard, etc. from rice hulls, coconut husks, wood residues
- Lightweight aggregates for concrete from dried rice hulls, carbonated non-edible grains
- Pozzolanic materials from rice hull ash
- Waterproof coatings from banana stalks (boiled in little water), cashew nutshell liquid resin.

Advantages:
- Extremely cheap raw materials
- Reduction of environmental problems caused by accumulation of waste

Disadvantages:
- Often insufficient availability, since much waste is being used as cheap fuel, even though the benefits of conversion into cheap building materials could be greater.

Remedies:
- Deeper research on technological aspects and cost/benefit analysis
- Legislative means in organizing waste reuse.

Industrial Waste

Applications:
- Aggregates for concrete from fly ash (moistened, nodulized and sintered), foamed blast furnace slag (by adding little water to molten slag)
- Hydraulic setting binders from fly ash and "surkhi" (pulverized brick and tile rejects, mainly used in India)
- Mineral wool (as filler for bitumen felt) from fly ash
- Waterproofing coats using sulphur.

Advantages:
- Same as for agricultural waste
- Well established technologies in many countries.

Disadvantages:
- Only in use of sulphur: high level of toxicity and odour at high temperature (50°C), brittleness, contraction during hardening. Necessity of application in molten state (problem of premature hardening) requiring special equipment
- Premature setting of fly ash in moist conditions.

Remedies:
- Research into low-cost sulphur-coating techniques
- Storage of fly-ash with same care as cement.

3.5 Verschiedene Gesichtspunkte

3.5.1 Dimensionen

Bei einfachen Dachkonstruktionen für den Wohnungsbau garantiert die traditionelle Bemessung und Montage der Bauelemente normalerweise eine adäquate und stabile Konstruktion. Jedoch, mit zunehmenden Spannweiten über das Optimum der jeweiligen Materialien hinaus, bewirken zunehmende Materialstärken (der statischen Bauteile und Dacheindeckung), Eigengewicht und Materialmengen, eine Verminderung der Wirtschaftlichkeit und limitieren die sinnvolle Ausnutzung der Materialeigenschaften. Eine Erhöhung der statischen Tiefe der Elementkrümmung, -faltung oder -wellung ist dann nötig, um einen Balkeneffekt zu erzeugen. Hierdurch kann ein verhältnismäßig dünnes Material benutzt werden für Spannweiten, die im Verhältnis zur Dicke der statischen Hülle sehr groß sind.

In bezug auf Höhen von abgehängten Decken oder flachen Dächern zeigten experimentelle Studien in Indien, daß die Erhöhung der Decken auf mehr als 2,70 m keine nennenswerten Temperaturvorteile zeigten, unabhängig von Ventilationsbedingungen und jahreszeitlichen Veränderungen.

Die Verwendung von Modulmaßen bei der Planung von Dächern ist noch nicht ausreichend verbreitet, doch besteht in den meisten Ländern eine Neigung, den Dezimeter als Grundmodul zu benutzen. Das Rastermaß muß ein Vielfaches des Grundmoduls sein (3, 6, 9, usw. sind übliche Multipeln), wobei es den Raum zwischen angrenzenden Komponenten mit einschließt, so daß die Komponentengröße kleiner ist als das Rastermaß. Die Modulmaßordnung kann auf diese Weise für Materialgrößen und Elementabstände, parallel zum Ortgang und zum First gemessen, angewandt werden. Die Hauptvorteile von Modulmaßen sind leichtere Montage, Austausch von Elementen durch andere Materialien, sowie Reduzierung der Materialverschwendung durch Verschnitt.

3.5 Miscellaneous Aspects

3.5.1 Dimensions

In simple domestic roof constructions, a tradition of member-sizing and assembly normally ensures an adequate and stable structure. However, as spans increase above the optimum for each material, increased thicknesses (of structural members and roof cover), dead weight and material usage make them inefficient and limit their capability. An increase of structural depth of the whole unit of curvature, folding or corrugation is then necessary in order to create a beam effect and by this means a basically thin material may be used over spans which are large in relation to the thickness of the structural surface.

As regards the heights of suspended ceilings or flat roofs, experimental studies undertaken in India have shown that raising the ceiling height above 2.70 m had no significant thermal advantage, irrespective of ventilation conditions and seasonal variations.

The use of modular coordination in roof design is still not sufficiently widespread, though there are tendencies in most countries to use the decimetre as the basic module. The modular dimension must be a multiple of the basic module (3, 6, 9, etc. are common multiples), and includes the space needed for joining the components, so that the component size is less than the modular dimension. Modular coordination can thus be applied to material sizes and spacing of members measured parallel to eaves and ridge. The main advantage of modular coordination is to facilitate assembly and even substitution of different materials and to reduce wastage due to cutting of excess material.

3.5.2 Dachneigungen

Dachneigungen werden oft in Grad angegeben (z.B. 15°, 20°, 22,5°), wahrscheinlich weil dieses leichter vor Augen zu führen ist. In der Praxis ist es jedoch sehr schwierig oder unmöglich für die Arbeiter auf der Baustelle oder in der Werkstatt, diese Winkel auszumessen. Deshalb werden Dachneigungen besser in dem einfachen Verhältnis zwischen Höhe und Spannweite angegeben (z.B. 1 : 1; 1 : 1,5; 1 : 2; 1 : 20), soweit möglich, unter Anwendung runder Zahlen.

Die Hauptfunktion der Dachneigung ist, Regenwasser ablaufen zu lassen, ehe es in das Dachmaterial eindringen kann. Je niedriger die Durchlässigkeit, desto weniger Dachneigung ist erforderlich. Jedes Dachdeckenmaterial hat demnach seinen eigenen optimalen Neigungswinkel. Einige der empfohlenen Mindestneigungen sind:

3.5.2 Roof Slopes

Inclinations of roofs are often given in degrees (eg. 15°, 20°, 22.5°), probably because these are easier to visualize. In practice, however, it is extremely difficult or impossible for workers on the site or in the workshop to measure out these angles. Therefore roof slopes are best expressed in simple relations between height and span (eg. 1 : 1, 1 : 1.5, 1 : 2, 1 : 20), preferably using round numbers.

The main function of roof slopes is to allow rainwater to run off before it is able to penetrate the roofing fabric. The lower the permeability, the less slope is required. Each roofing material therefore has its own appropriate pitch. Some recommended minimum slopes are:

Dachdeckenmaterial	erforderliche Mindestneigungen	
	Verhältnis	Winkel
Grasdeckung	1 : 1	45°
Holzschindeln:		
- unbehandeltes Holz	1 : 1	45°
- druckbehandeltes Holz	1 : 1,5	33°40′
Gebrannte Dachziegel:		
- Biberschwanz- und Mönch- und Nonnendeckung	1 : 1,5	33°40′
- Flachdachpfannendeckung (ohne wasserdichte Folie)	1 : 2	26°40′
- Flachdachpfannendeckung (mit wasserdichter Folie)	1 : 3	18°30′
Verzinktes Wellblech:		
- mit Überlappungen (d.h. mehr als eine Platte in Fallrichtung)	1 : 3	18°30′
- ohne Überlappung (d.h. eine Platte zwischen First und Traufe)	1 : 5	11°20′
Asbestzementplatten:		
- gewellt (mit Überlappungen)	1 : 3	18°30′
- gewellt (ohne Überlappung)	1 : 5	11°20′
- trogförmig (ohne Überlappung)	1 : 10	5°40′

3.5.3 Statisches Verhalten

Für die statische Festigkeit und Stabilität eines Daches muß sowohl das Eigengewicht als auch die Verkehrslasten berücksichtigt werden. Ersteres besteht aus dem Eigengewicht der Dachkonstruktion und der Dachhaut sowie aus den statischen Lasten von Geräten und Anlagen, die auf oder unter dem Dach befestigt sind. Haupterfordernis ist es, ein geringeres Eigengewicht pro Flächeneinheit zu erreichen, je länger die Spannweite ist (siehe 3.5.1 Dimensionen). Dies steht jedoch im Gegensatz zur Notwendigkeit dickwandiger Konstruktionen, um die Schallübertragung zu reduzieren, besonders der der Aufprallgeräusche von Regen und Hagel. Verkehrslasten sind jene, die durch Winddruck und Begehung des Daches hervorgerufen werden. In einigen Wüstengebieten muß mit Sandablagerungen gerechnet werden. Wo Erdbeben und Wirbelstürme erwartet werden, müssen besondere Entwurfsprinzipien beachtet werden, um ernste Schäden zu vermeiden.

Es muß jedoch betont werden, daß die statische Zulänglichkeit eines Daches zum größten Teil vom übrigen Gebäude abhängt, z.B. bei Häusern (mit unzureichendem

Roof covering material	Minimum slope required	
	Ratio	Angle
Grass thatching	1 : 1	45°
Timber shingles:		
- untreated timber	1 : 1	45°
- pressure impregnated timber	1 : 1.5	33°40′
Burnt clay roof tiles:		
- plain tiles and Spanish type	1 : 1.5	33°40′
- Roman type (without waterproofing membrane)	1 : 2	26°40′
- Roman type (with waterproofing membrane)	1 : 3	18°30′
Corrugated galvanized iron sheets:		
- with end laps (ie more than one sheet in direction of fall)	1 : 3	18°30′
- with no end laps (ie one sheet between ridge and eaves)	1 : 5	11°20′
Asbestos cement sheets:		
- corrugated (with end laps)	1 : 3	18°30′
- corrugated (with no end laps)	1 : 5	11°20′
- troughed (with no end laps)	1 : 10	5°40′

3.5.3 Structural Performance

For the structural strength and stability of a roof, attention must be given both to its dead load and imposed loads. The former consists of the self-weight of the roof structure and its claddings and any other static loads from equipment carried on or suspended from the roof. The principal requirement is to achieve lower dead weight per unit area, the longer the span is (see 3.5.1 Dimensions). This, however, is in conflict with the need for heavy mass for reduction of sound transmission, especially of impact noise from the drumming of rain and hail. Imposed loads comprise those due to wind forces and moving traffic. In some desert regions sand deposition in sandstorms may have to be taken into account. Where earthquakes or hurricanes are to be expected, special design principles must be observed to avoid serious damage.

It must, however, be stressed that the structural performance of a roof largely depends on the rest of the building, eg. with houses (having poor or no foundations) built on expansive soils, swelling and contracting of the ground can cause serious failures of building elements and their joints. Similarly, failure of walls under seis-

oder keinem Fundament), die auf dehnbarem Boden gebaut wurden, kann Schwellen und Zusammenziehen des Bodens zu folgenschwerem Versagen der Bauelemente und deren Verbindungen führen. Ähnlich kann das Versagen von Wänden unter seismischen Kräften den Zusammenbruch des Daches verursachen. Daher ist die Anbringung eines durchgehenden Ringbalkens entlang der Oberkante der Wände, die das Dach tragen, oft eine der wichtigsten Anforderungen. Alternativ dazu sichert eine völlige statische Trennung der Dachkonstruktion von den Wänden, indem also die Last über unabhängige Stützen direkt zum Fundament geführt wird, Stabilität, selbst wenn die Wände zusammenbrechen.

3.5.4 Wärme- und Feuchtigkeitsbewegungen

Die Aufnahme von Sonnenenergie während des Tages und der Abfluß von langwelliger Rückstrahlung während der Nacht bedeutet, daß Dächer in den Tropen relativ großen Temperaturschwankungen ausgesetzt sind, wobei die größten Temperaturspannen in den trockenen Tropen auftreten. Die resultierenden Wärmeausdehnungen und Schrumpfungen können zu ernsten Schäden der Dachelemente führen.

Je nach Art der Materialien, die dafür verwendet werden, kann die Dachkonstruktion Feuchtigkeitsbewegungen ausgesetzt sein, hervorgerufen durch das anhaltende Schrumpfen von Materialien, wie zum Beispiel austrocknendem Zement, und durch periodische Veränderungen der relativen Feuchtigkeit. In geringem Maße sind Verbiegungen und Verdrehungen statisch nicht immer schädigend, könnten aber bei Naturkatastrophen, wie Erdbeben und Wirbelstürmen, ein Risiko darstellen.

Um Wärme- und Feuchtigkeitsbewegungen entgegenzuwirken oder die Schäden auf einem Minimum zu halten, wären die folgenden Punkte von Interesse:

a. Ziegel-, Schindel- oder Wellplattendächer nehmen Wärmebewegungen durch verschiebbare Überlappung und flexible Materialien auf. Gefaltete oder gerundete Oberflächen nehmen die Bewegung durch Erhöhung und Vertiefung der Krümmungsprofile auf.

b. Starre Betonplatten und dünnwandige Dächer sollten oberhalb der Platte ausreichend isoliert sein, und die äußere Oberfläche sollte durch reflektierende Anstriche oder Beschattungsvorrichtungen geschützt sein.

c. Bewegungsfugen sollten bei Dächern vorgesehen werden, um relative Bewegungen zuzulassen, ohne die Dachkonstruktion zu schädigen oder zu schwächen. Ungeschützte Bewegungsfugen müssen völlig wasserdicht sein.

mic forces can cause roofs to collapse. Therefore the provision of a continuous ring beam along the top edge of the walls supporting the roof is often a prime necessity. Alternatively, a complete structural separation of the roof construction from the walls, transmitting loads via independent columns directly to the foundations, ensures stability even if the walls fail.

3.5.4 Thermal and Moisture Movement

The absorption of solar energy during the day and emission of long-wave radiation at night can mean that roofs in tropical areas can be subjected to fairly large ranges of temperature, the larger temperature ranges occuring in the dry tropics. The resulting thermal expansion and contraction can cause serious damage to roof components.

Depending on the materials used in its construction, the roof can also be affected by moisture movement, caused by permanent shrinkage of materials, such as concrete drying out, and by periodic changes in relative humidity. Within limits, deflection and distortion is not always structurally damaging, but could be a hazard in natural disasters, such as earthquakes and hurricanes.

To counteract thermal and moisture movement or minimize damage caused by it, the following points are of interest:

a. Tiled, shingled or corrugated-sheet roofs take up thermal movement by sliding overlaps and flexibility of materials. Folded or curved surfaces take the movement by a rise and fall of the curved profiles.

b. Rigid concrete slab and membrane roofs should be efficiently insulated above the slab and the outer surface should be protected by application of reflective coating or shading devices.

c. Movement joints should be provided in roofs to permit the relative movements to take place without damaging or weakening the roof structure. Exposed movement joints must be completely waterproof.

3.5.5 Wirtschaftliche Überlegungen

Selbst wenn zuverlässige Kostenvergleiche über Dachkonstruktionen vorhanden wären, hätten diese wenig praktischen Wert, da Dachentwürfe, Konstruktionsmethoden, Arbeits- und Materialkosten von Gebiet zu Gebiet sehr verschieden sind. Einige kostenbeeinflussende Prinzipien bestehen jedoch und sollten bei der Planung und Ausführung von Dächern berücksichtigt werden.

Die Anwendung eines Systems nahe an seinen größtmöglichen Spannweiten resultiert normalerweise in hohen Fertigungs-, Transport- und Montagekosten. Dies erfordert kleine Raumdimensionen, aber aus verschiedenen anderen Gründen ist dies bereits eines der Hauptmerkmale der Niedrigkosten-Bauweise.

Die anfänglichen Kosten auf einem Minimum zu halten, kann hohe Ausgaben für Instandhaltung und Reparaturen bedeuten. Schlecht entworfene Dächer können zu verminderter Leistungsfähigkeit und schlechtem Gesundheitszustand der Bewohner führen, welche ebenso wichtige Kostenfaktoren sind. Erhebliche Kenntnisse über örtliche Materialien, Preise und Facharbeit sowie über die Bedingungen, denen das Dach ausgesetzt ist, sind daher erforderlich, um einen wirtschaftlich geeigneten Dachentwurf zu finden.

Vorfertigung als ein kostenreduzierender Faktor hat begrenzte Anwendung für den Niedrigkosten-Wohnungsbau, außer für die Herstellung von Wellblech oder verstärkte Leichtbauplatten. Fertigbaukonstruktion, wie sie normalerweise verstanden wird, heißt Vorfertigung von großen Platten oder ganzen Dächern, was spezialisierte und teure Montagewerkzeuge erfordert. Leichte Handhabung und Baumethoden sind deshalb wichtiger als Vorfertigung.

Je einfacher der Entwurf und Bauablauf, desto besser und billiger wird im allgemeinen das System sein. Es sollte eine für Arbeiter einfach erlernbare Konstruktionsmethode vorsehen, den Einsatz von manueller Arbeit anstatt von teurem, kompliziertem Arbeitsgerät erfordern, nur örtlich vorhandenes, nicht-importiertes Material verwenden und Ungenauigkeiten tolerieren. Das ist in den Entwicklungsländern, wo Fachkräfte und kompetentes Aufsichtspersonal nicht ausreichend verfügbar sind, von besonderer Wichtigkeit.

3.5.5 Economic Considerations

Even if reliable cost comparisons of roof constructions were available, they would be of little practical value, as roof designs, construction methods, labour and material costs differ so greatly from region to region. A few principles governing cost do however exist and should be considered in roof design and construction.

The use of a system at the upper limits of its span capability normally results in higher costs of fabrication, transportation and assembly. This calls for small room dimensions, but, for a number of other reasons, this already is a common feature of low-cost housing design.

Keeping initial costs at a minimum may mean high expenses for maintenance and repair over long periods. Poorly designed roofs can result in reduced efficiency and bad health of the occupants, which are equally important cost factors. It therefore requires considerable knowledge of local materials, prices and workmanship, as well as the conditions to which the roofs are subjected, to find the economically most appropriate roof design.

Prefabrication as a factor of cost reduction has limited application in low-cost housing, except for the manufacture of corrugated or strengthened lightweight sheeting. Prefabricated construction, as it is normally understood, means prefabrication of large panels or whole roofs, which need specialized and expensive installing equipment. Ease of handling and erection therefore are of more importance than prefabrication.

In general the simpler the design and procedure, the better and cheaper the system will be. It should be easy for workers to learn construction methods, make use of manual labour rather than expensive, complicated equipment, use only locally available, non-imported material and tolerate inaccuracies. This is especially important in developing countries where skilled labour and competent supervisory staff can be in short supply.

4. ALLGEMEINE ÜBERSICHT ÜBER NIEDRIGKOSTEN-DACHSYSTEME

4.1 Herkömmliche Systeme

4.1.1 Traditionelle Dächer

Einheimische Häuser, in allen Teilen der Welt, haben zunehmend das Interesse von Architekten und Ingenieuren geweckt, nicht nur weil jedes traditionelle Bauwerk ein Stück Kunst ist, das oft handwerkliche Geschicklichkeit vorführt, die beim "modernen Mann" längst ausgestorben ist, sondern hauptsächlich, weil (mit ein paar Ausnahmen)viel über Gebäude-Klimatologie, Materialverwendung, Gefühl für Proportionen und den menschlichen Maßstab, Wirtschaftlichkeit bei Konstruktion und Instandhaltung sowie Interpretation von örtlichen Kulturen und menschlichen Bedürfnissen zu lernen ist. Die folgende Tabelle (welche aus naheliegenden Gründen nur eine sehr kleine Auswahl von mehreren tausend möglichen Beispielen ist) gibt eine allgemeine Vorstellung über die Vielfalt der Formen und Konstruktionen, wovon einige durch Zeichnungen detaillierter erläutert werden.

4. GLOBAL REVIEW OF LOW-COST ROOFING SYSTEMS

4.1 Systems in Common Usage

4.1.1 Traditional Roofs

Indigenous houses in all parts of the world have increasingly captured the interest of architects and engineers, not only because each traditional structure is a work of art, often displaying skills long extinct in "modern" man, but mainly because (apart from a few exceptions) much can be learnt from them with respect to building climatology, use of materials, sense of proportions and human scale, economy of construction and maintenance, and translation of local cultures and human needs.
The chart below (which for obvious reasons is only a minute selection from several thousand possible examples) gives a general idea of the diversity of forms and constructions, some of which are described by means of diagrams in more detail.

Abb. 4.1 Masai-Häuser (Kenia, Tansania)

Fig. 4.2 Pueblo houses (Southwestern United States)

Haustyp Volksstamm/Kultur Land/Region	Materialien und Konstruktionen	Bemerkungen
FLACHE DÄCHER		
Dachgrundriß: oval oder rechteckig		
Boma der Masai, Kenia, Tansania	Fachwerk aus Ästen, mit Gras und Zweigen zusammengeflochten. Glatte Oberflächenbehandlung mit frischem Kuhdung. Zusätzliche Wasserfestigkeit mit Häuten. Schmale Tür als einzige Öffnung.	Frauen sind für Bauarbeiten verantwortlich. Sparsam mit Materialien und Aufwand, daher Höhe des Daches zu niedrig, um aufrecht zu stehen. Kleine Feuer brennen dauernd, füllen Raum mit Rauch. Stromlinienform (gerundete Ecken) und -oberflächenbearbeitung von Vorteil in windigen Gegenden.
Dachgrundriß: quadratisch oder rechteckig		
Pueblo-Behausungen z.B. der Hopi und Zuni, Südwest Vereinigte Staaten	Drei- bis fünfgeschossige Terrassenbebauung aus Lehmziegeln oder Steinen, mit Lehm verputzt. Dach bestehend aus geschälten Zederbalken, überdeckt mit kleinen Rundhölzern, Zederrinde und Gras, welches eine 10 cm dicke Lehmschicht trägt. Nur ein paar kleine Öffnungen in den äußeren Wänden.	Eingänge der Pueblos:hauptsächlich mittels Leitern erreichbare Öffnungen im Dach. Benutzung der Dächer zum Sitzen, Schlafen und Arbeiten. Da dicke Zederbalken in trockenen Zonen rar sind, werden sie nicht auf die erforderliche Länge geschnitten, sondern durchdringen die Außenwand und kragen beliebig weit aus. Diese Balken werden über Jahrhunderte immer wieder verwendet.
Compounds Hausa, Nord-Nigeria	Wände aus birnenförmigen Lehmziegeln und verputzt, Lehmdächer verstärkt durch Holz und Palmenzweige.	Alternativ gewölbte Dächer. Symbolische Dekorationen am Dachrand entlang und an den Wänden sehr charakteristisch.

House Type, Tribe/Culture Country/Region	Materials and Constructions	Comments
FLAT ROOFS		
Roof Base: oval or rectangular		
Bama of the Masai, Kenya, Tanzania	Framework of branches, interwoven with grass and twigs. Smooth surface finish with fresh cow dung. Additional water-proofing with layer of hides. Narrow door is the only opening.	Women responsible for building. Economy of materials and effort hence height of roof too low to stand upright. Small fires constantly burning in hut, fill rooms with smoke. Streamlined shape (corners rounded) and finish are advantageous in windy environment.
Roof Base: square or rectangular		
Pueblo dwellings eg. of Hopi and Zuni, Southwestern United States	Three to five storeyed, terraced houses of adobe brick or stone in adobe mortar, plastered with clay mud. Roofs consist of peeled cedar beams covered with small poles, cedar bark and grass, which support 10 cm coat of adobe. Only few small openings on exterior walls.	Access to pueblos generally through openings in roof, using ladders. Roofs used for sitting, sleeping, working. Since the thick cedar beams are rare in arid regions, they are not cut to required lengths, but allowed to project through face of exterior walls. These beams are used over again for hundreds of years.
Compounds Hausa, Northern Nigeria	Walls made of pear-shaped mud-bricks and plastered over. Mud roofs reinforced with wood or palm fronds.	Alternatively roofs are vaulted. Symbolic decorations along roof edges and walls are very characteristic.

Haustyp Volksstamm/Kultur Land/Region	Materialien und Konstruktionen	Bemerkungen
Innenhofhäuser, Dogon, Mali	Gruppenbehausungen mit lehmverputzten Lehmziegelwänden. Lehmverputzte Dächer ruhen auf Holzsparren, -balken und -stützen, wo erforderlich. Vorgefertigte konische Strohdächer bedecken zusätzlich flache Dächer von Getreidespeichern.	Häuseranordnung nach kosmologischem Schema, Mindestdimensionen, zweistöckig. Balken und Sparren, die aus den Außenwänden auskragen, werden als Gerüst für Konstruktion und Reparaturen am Haus benutzt. Konische Strohdächer auf viereckiger Grundfläche ergeben wellige Trauflinie.
Untergrundhäuser, z.B. Matmata, Sahara und Honnan, China	Behausungen aus weicher, poröser Erde geschnitten. Erdoberfläche selbst bildet das Dach.	Nutzung der unerschöpflichen Wärmekapazität der Erde: warm im Winter, kühl im Sommer.
Mehrgeschossige Häuser, Nordafrika und Mittlerer Osten	Hauptmaterial Lehm mit pflanzlicher Bewehrung, manchmal gebackene Lehmziegel. Dächer meistens aus Holz und Lehm.	Dächer häufig zum Schlafen benutzt. Konstruktion für überwiegend trockene Zonen geeignet. Oft Windtürme auf den Dächern, um Brisen ins Innere zu lenken.
PULTDÄCHER		
Windbrecher bei nomadischen Stämmen in vielen Ländern, z.B. Nordafrika, Türkei, Malaysia, Australien	Ganzes Bauwerk bestehend aus dem Dach und den tragenden Elementen (keine Wände), meistens an drei Seiten offen. Pflanzenmaterialien, die örtlich gefunden werden, leichte Matten oder Textilien.	Einzige Funktion: Schattenspenden und Schutz vor dem vorherrschenden Wind. Überraschend oft anzutreffen in Gebieten mit rauhem Klima, was dicht umschlossene Lebensräume aus isolierenden Materialien erfordert.

House Type, Tribe/Culture Country/Region	Materials and Constructions	Comments
Courtyard houses, Dogon, Mali	Cluster dwellings with mud plastered adobe walls. Mud plastered roofs rest on wooden rafters, beams and columns where necessary. Prefabricated conical straw roofs additionally cover flat roofs of graneries.	Layout of houses according to cosmological scheme, minimum dimensions, two storeys high. Beams and rafters penetrating exterior walls used as scaffoldings in construction and repair of houses. Conical straw roofs on square base make eaves always uneven.
Underground houses eg Matmata, Sahara and Honnan, China	Dwellings cut out of soft porous soil. Ground surface constitutes the roof.	Use is made of infinite heat capacity of earth: warm in winter, cool in summer.
Multistoreyed houses, North Africa and Middle East	Primary material mud with plant reinforcements, sometimes burnt clay bricks. Roofs usually of timber and mud.	Roofs frequently used for sleeping. Construction appropriate for predominantly hot dry regions. Often wind towers on roofs to divert breeze to interior.
SINGLE PITCHED ROOFS		
Windbreaks used by nomadic tribes in many countries, eg North Africa, Turkey, Malaysia, Australia	Entire structure consisting of roof and supporting members (no walls), usually open on three sides. Plant materials found locally or light matting or textiles brought by dwellers.	Only function is to give shade and protection from prevailing winds. Surprisingly often used in regions with harsh climates, requiring well enclosed spaces with insulating materials.

Fig. 4.7 Windbreak

Haustyp Volksstamm/Kultur Land/Region	Materialien und Konstruktionen	Bemerkungen
SATTEL- UND WALMDÄCHER		
Dachgrundriß: oval oder rechteckig		
Behausung der Maya, Yucatan-Halbinsel (Mexiko, Guatemala), sehr den Häusern auf den Fidschi-Inseln ähnlich	Einfache 1-Zimmer-Häuser mit ovalem Grundriß und Walmdächern. Leichte Wände aus Maisstengeln, gewebtem gespaltenem Bambus oder Flechtwerk mit Lehm (Bajareque). Bei fidschianischen Dächern Firstpfetten auf beiden Seiten auskragend.	Symmetrischer Entwurf mit Tür in der Mitte einer Breitseite. Gefahr des Niederbrennens des Hauses durch Kochen im Hausinneren mit offenen Feuern, aber Rauchentwicklung hilft Insekten und Tiere fernzuhalten.
Malocas der Indianer-Stämme im Amazonas-Becken	Große Gemeinschaftshäuser aus örtlichem Holz, Bambus, Gräsern und Blättern, um eine dicke Gebäudehülle zu schaffen. Ziemlich steile Dächer, die meistens am Boden beginnen. Keine Öffnungen, außer kleinem Eingang.	Wegen fehlender Ventilation und großer Wärmespeicherkapazität des dicken Daches müssen die Häuser in heißen Sommermonaten verlassen werden.
Dachgrundriß: rechteckig		
Totora-Häuser, Uru-Indianer, Titicacasee, Peru	Gebäude nur aus einem Material hergestellt — Totora — ein Schilf, das im See wächst. Wände aus Schilfbündeln, Dächer aus Schilfmatten.	Häuser gebaut auf künstlichen Schilf-Inseln, die auf dem See wie ein Floß schwimmen. Da die Inseln allmählich sinken, dauernde Erneuerung des Schilfs nötig.
Gemeinschaftshäuser, Yagua-Indianer, Peruanischer Amazonas	Wandlose Häuser mit Walm- oder Satteldächern. Holzrahmenkonstruktion mit Grasdach. Erhöhte Plattform aus gespaltenem Bambus.	Bestgeeignete Konstruktion für feuchttropisches Klima. Obwohl völlig offenes Gebäude, Privatsphäre erreicht durch Abwenden vom Zentrum des Hauses (kulturelle Konvention).

House Type, Tribe/Culture Country/Region	Materials and Constructions	Comments
DOUBLE PITCHED AND HIP ROOFS		
Roof Base: oval or rectangular		
Dwellings of Maya, Yucatan Peninsula (Mexico, Guatemala), very similar to houses on Fiji Islands	Simple one-room homes with oval plan and hip roofs. Light walls of corn stalks, woven split bamboo or wattle and daub (bajareque). Steep thatched roof. Fijian roofs have ridge poles protruding from each end.	Symmetrical design with door in centre of one broad side. Cooking with open fires in interior constitute risk of house burning down, but smoke helps to eliminate insects and pests.
Malocas of Indian tribes in the Amazon Basin	Large communal houses made of local timber bamboo, gresses and leaves to form thick building envelope. Fairly steep roofs, usually beginning at ground level, and no openings besides small entrance.	Due to lack of ventilation and large heat retaining capacity of thick roof, houses must be abandoned during hot summer months.
Roof Base: rectangular		
Totora houses, Uru Indians, Lake Titicaca, Peru	Buildings made only from one material — totora — a reed growing in the lake. Walls of reed bundles, roofs of reed mats.	Houses are built on artificial islands also made of reeds floating on the lake. Since islands gradually sink, constant renewal of reeds is necessary.
Communal houses, Yagua Indians, Peruvian Amazon	Open-walled hipped or gable roofed houses on piles. Timber frame structure with thatch roofs. Raised platform of split bamboo.	Most appropriate construction for the damp tropical climate. Though completely open building, privacy is obtained simply by turning away from centre of house (cultural convention).

Fig. 4.11 Communal house of Yagua Indians (Peruvian Amazon)

Haustyp Volksstamm/Kultur Land/Region	Materialien und Konstruktionen	Bemerkungen
Innenhofhäuser Asante Ghana	Rechtwinklige Häuser. Wände aus dickflüssigem Lehm mit Bewehrung aus Rohr, steiles Satteldach aus Gras.	Normalerweise vier separate Gebäude, im rechten Winkel um den Innenhof herum angeordnet; einige der zum Innenhof gerichteten Seiten sind offen oder haben Stützen (Palmzweige, bedeckt mit Lehm).
Stelzenhäuser Kokwê-See, Benin	Tragkonstruktion aus Holz (Mangrove), Wandausfachungen aus Palmen oder gespaltenem Bambus hergestellt, Dachstuhl aus Palmzweigen mit Grasdeckung.	Keine absolute Übereinstimmung bei Wahl der Dachform. Möglichkeit der individuellen Gestaltung. Bei manchen Walmdächern elegant geschwungene Linie bis zum First.
KONISCHE UND BIENENKORBFÖRMIGE DÄCHER		
Dachgrundriß: rund		
Tepee, Wigwam Flachland-Indianer, Nordamerika	Kiefernpfähle, kreisförmig in die Erde gesteckt und am oberen Ende zusammengebunden, um eine konische Form zu bilden. Äußere Eindeckung aus Büffelhaut, mit einem Loch am oberen Ende als Rauchabzug.	Anstatt der Häute wird auch Birkenrinde benutzt. Durch lange Stöcke betätigte Klappen an der Zeltspitze, um Rauch abzuführen, ohne Zugluft hereinzulassen. Einfacher Aufbau, Abbau und Transport der Zelte.
Rundhäuser z.B. Lasso in Togo und Hutu in Ruanda	Kreisförmige Wände aus gestampftem Lehm mit konischen Strohdächern.	Häufigster Dachtyp in Afrika. Steile Neigungswinkel, um Regenwasser schnell ablaufen zu lassen. Erneuerung nur jedes zweite Jahr erforderlich.
Behausungen der Mousgoum, Nord-Kamerun	Häuser ausschließlich aus Lehm, ohne Schalung gebaut (echte Kuppelbauweise), charakteristisches Reliefmuster der Außenflächen.	Bedeutung der äußeren Muster nicht bekannt, aber sie ermöglichen der Aufstieg zur Spitze, verleihen dem Bauwerk zusätzliche Festigkeit und verhindern Entstehung von Erosionsrinnen durch Regenwasser.

House Type, Tribe/Culture Country/Region	Materials and Constructions	Comments
Courtyard houses Asante, Ghana	Rectangular houses, walls made of pudded mud reinforced with cane, steep thatched saddle back roof.	Usually four separate buildings arranged at right angles around courtyard; some of the sides facing court are open or pillared (palm frond covered with mud).
Pile dwellings Lake Nokwê, Benin	Basic structure of timber (mangrove), walls of infill panels of palm or split bamboo. Roof made of palm frond structural framework with thick grass thatch.	No absolute consistency in roof design. Some hipped roofs have elegant curves to the ridge.
CONICAL AND BEEHIVE SHAPED ROOFS		
Roof Base: circular		
Tepee, Wigwam Plains Indians, North America	Poles of pine stuck in the ground in a circle and tied together at upper end to form conical shape. Outer skin of buffalo hide, leaving hole at the top for smoke to escape.	Instead of hides, also birch bark cover in common use. Two flaps at top end, adjusted by longer poles control ventilation, letting smoke escape without draughts entering. Easy erection, dismantling and transportation of tent.
Round houses e.g. Lasso of Togo and Hutu of Rwanda	Circular walls of compacted mud with conical thatch roof.	Most common roof type in Africa. Steep pitches allow rapid run-off of rainwater. Renewal required only every second year.
Dwellings of the Mousgoum, Northern Cameroon	Houses built entirely of mud with no formers (true dome construction). Significant relief pattern on outer surface.	Meaning of exterior patterns not known, but facilitates climbing to top, adds strength to structure and prevents erosion channels by rainwater.

Haustyp Volksstamm/Kultur Land/Region	Materialien und Konstruktionen	Bemerkungen
Behausungen der Sidamo, Äthiopien	Gerüst aus flexiblen Stangen, in die Erde gebettet und oben unter Spannung zusammengebunden. Äußere Bedeckung aus gespaltenem Bambus, korbartig geflochten.	Extrem standfeste Konstruktion, keine Absackung durch das Gewicht mehrerer Männer auf dem Dach.
Dachgrundriß: quadratisch		
Behausungen der Bamileke, Kamerun	Wände, quadratisch angeordnet, aus Palmzweigen oder Bambus mit Lehmausfachung. Plattform als Dachbasis auf dem Boden vorgefertigt. Konisches Raumfachwerk als Dachstuhl; Strohdeckung.	Ungewöhnliche Hausform. Wichtige Häuser zusätzlich entlang der Dachkante mit Stützen umringt, um Veranda zu bilden.
Trulli, Murgia, Italien	Rechteckige Häuser mit quadratischen Zimmern, jedes mit einem konischen Dach. Gesamte Konstruktion (Wände u. Dach) aus flachen Steinen ohne Mörtel verlegt. Abschlußstein an der Dachspitze mit Kalkschlämme bestrichen, sonst keine Außenbeschichtung.	Trulli im Sommer angenehm kühl, im Winter kalt und feucht. Regenwassersammlung vom Dach.
Dachgrundriß: freie Form		
Felsenbehausungen, Göremetal in Anatolien, Türkei	Durch Wind- und Wassererosion natürlich geformte konische Felsen. Behausungen aus weichem Stein herausgeschnitten, d.h. Konstruktion "durch Subtraktion".	Göreme-Kegel meist mehrgeschossig, bis zu 16 Geschossen. Zugang oft nur mittels Strickleiter.

House Type, Tribe/Culture Country/Region	Materials and Constructions	Comments
Dwellings of the Sidamo, Ethiopia	Framework of flexible poles embedded in ground and tied at top under tension. Outer cover of split bamboo woven like basket.	Extremely stable construction, no sagging under weight of several men standing on roof.
Roof Base: square		
Dwellings of the Bamileke, Cameroon	Walls, square in plan, built of palm fronds or bamboo infilled with mud. Platform of roof prefabricated on ground. Conical thatched roof supported by spaceframe.	Unusual house form. Important houses are ringed by pillars below roof edge to form a verandah.
Trulli, Murgia, Italy	Rectangular houses with square rooms, each capped by conical roof. Entire construction (walls and roof) made of flat stones laid without mortar. Cap stone of roof lime plastered, otherwise no outer coating.	In summer trulli are comfortably cool, in winter cold and damp. Rainwater is collected from roofs.
Roof Base: free form		
Rock dwellings, Anatolian valley of Göreme, Turkey	Naturally formed conical rocks, eroded by wind and water. Dwellings were cut out of soft stone, i.e. construction "by subtraction".	Göreme cones mostly multistoreyed, up to 16 floors. Access is often by rope ladder.

HALBKUGELFÖRMIGE DÄCHER		
Dachgrundriß: rund		
Yurt (Ger) Nomadische Stämme in Zentralasien (von der Türkei bis zur Mongolei)	Transportable Häuser mit Wänden aus faltbarem, leichtem Weidenholzgitterwerk, befestigt an Pfosten, die fest im Boden stehen. Dachrahmen aus Radialstäben mit hölzernem Druckring, der als Rauchzug fungiert. Außenhülle aus mehrlagigen Tierfellen, durch Seile befestigt.	Yurtform kann von Stamm zu Stamm variieren. Bietet sehr guten Schutz gegen rauhes Klima, besonders gegen starke Winde, aufgrund der Windschlüpfrigkeit. Rauchzug kann mit Fellstück durch Ziehen eines Stricks geschlossen werden.
Hogan Navajo-Indianer Südwest-Vereinigte Staaten	Einfamilienbehausung, in flachen Gruben gebaut, mit gabelförmigen Pfosten (meistens krumme), die Balken- und Lattenkonstruktion tragen. Kugelförmige Außenverkleidung durch Astgeflecht und dicken Lehmauftrag.	Innenraumklima ausgesprochen gut aufgrund hoher Wärmekapazität der Gebäudehülle. Keine Fenster vorhanden, lediglich Rauchzug im Dach und Tür in Ostrichtung.
Behausungen der Zulu, Swazi, Bantu Südafrika	Perfekte halbkugelförmige Bauwerke mit Grundgerüst aus gebogenen Schößlingen, mit Matten und Gras bedeckt und über gesamte Außenfläche netzartig mit Seilen zusammengebunden.	Hervorragende Wärmeisolierungseigenschaften der Konstruktion für Temperaturschwankungen zwischen 35°C und -4°C.

House Type, Tribe/Culture Country/Region	Materials and Constructions	Comments
HEMISPHERICAL ROOFS		
Roof Base: circular		
Yurt (Ger) Nomadic tribes in Central Asia (from Turkey to Mongolia)	Portable dwellings with walls of foldable lightweight willow latticework, lashed to poles firmly fixed in ground. Roof frame formed by radial poles fitted into wooden compression ring, which also serves as smoke hole. Outer cover made of several layers of felt held by ropes.	Design of yurt may vary from tribe to tribe. Displays high degree of protection against inclemency of weather, particularly strong winds, due to streamlined shape. Smoke hole may be closed by piece of felt drawn across by string.
Hogan Navajo Indians, Southwest United States	Single family dwellings, erected in shallow pit with forked posts (usually crooked) supporting beam and pole structure, covered by branches and thick soil layer, forming dome shape.	Indoor climate extremely good due to high heat capacity of building fabric. No windows are provided, only smoke hole in the roof and door facing the east.
Dwellings of the Zulu, Swazi, Bantu, South Africa	Perfect dome shaped structures made by basic framework of hoops, covered with mats, grass thatch and bound by network of rope.	Construction provides excellent insulation against temperature variations between 35°C and -4°C.

Haustyp Volksstamm/Kultur Land/Region	Materialien und Konstruktionen	Bemerkungen
Gemeinschaftshäuser, West-Samoa	Gebäude hauptsächlich bestehend aus kreisförmig angeordneten Holzstützen, die Dach aus geflochtenem Bambus mit Palm- oder Grasdeckung tragen.	Klimatisch geeignete Bauweise, jedoch nur zum Schlafen und Lagern verwendet. Gerollte Matten können entlang des Dachrandes heruntergelassen werden: zur Beschattung, ohne Beeinträchtigung der Querlüftung.
Dachgrundriß: quadratisch oder rechteckig		
Zelt, Tuareg, Sahara-Wüste	Transportable Behausungen aus mehreren schmalen Akazienstangen und -latten (oder Palmenästen) zu kuppelförmiger Rahmenkonstruktion zusammengebunden. Außenhülle aus fest angebundenen Grasmatten oder Häuten.	Mögliche Regenwasserdurchdringung der Matten; undurchlässige Hautverkleidungen im Sommer höchst unangenehm. Wegen starker Abkühlung während der Nacht Öffnung nach Osten gerichtet, um wärmende Sonnenstrahlen morgens einzufangen.
Kuppelbauten des Mittleren Ostens	Wände aus Bruchstein; Gewölbe und Bögen aus Lehmziegeln; glatte Oberfläche aus Lehmputz.	Hohe Festigkeit durch Doppelkrümmung, aber echte Kuppeln haben ungenügende Resistenz bei schweren Erdbeben.
TONNENFÖRMIGE DÄCHER		
Dachgrundriß: quadratisch oder rechteckig		
Ghorfas und andere traditionelle Häuser in Nordafrika	Bauten aus einem oder mehreren Geschossen gewölbter Zellen, gebaut aus Stein oder Lehmziegeln ohne Schalung.	Geniale Methode der Verlegung dreidimensionaler Ziegelschichten, so daß jeder Ziegel von den darunterliegenden getragen wird. Stabile, klimatisch angepaßte Bauweise, jedoch nicht erdbebenresistent.

House Type, Tribe/Culture Country/Region	Materials and Constructions	Comments
Communal dwelling Western Samoa	House basically consists of circle of timber columns supporting roof framework of woven bamboo and palm or grass thatch.	Climatically appropriate design, but merely used for sleeping and storage. Rolled up mats may be unfurled from roofs to provide shade and utilize breezes.
Roof Base: square or rectangular		
Tent, Tuareg, Sahara Desert	Portable dwelling consisting of several slim poles and laths from acacia or palm fronds laced to form dome shaped framework. Grass mats or skin tied down firmly, form the outer cover.	During rains mat covers tend to leak, in hot season impermeable skin covers are most unpleasant. Since temperatures drop sharply at night, open fronts face the east to catch warming rays of morning sun.
Domed houses of the Middle East	Walls made of stone rubble; vaults and arches of mud brick; smooth surface of mud plaster.	Good strength due to double curvature, but true domes have insufficient resistance in heavy earthquakes.
BARREL VAULTS		
Roof Base: square or rectangular		
Ghorfas and other traditional houses in North Africa	Structures consisting of one or several storeys of vaulted cells, built of stone or mud brick without shuttering.	Ingenious method of laying three-dimensional courses, such that each brick rests on the ones below. Stable and climatically appropriate structure, but not earthquake resistant.

Haustyp Volksstamm/Kultur Land/Region	Materialien und Konstruktionen	Bemerkungen
Mudhifs der Madan (Sumpf-Araber), Süd-Irak	Gebündeltes Riesenschilf, in den Boden gesteckt und zu Bögen zusammengebunden; Außenverkleidung mit Matten aus gespaltenem Schilf.	6000 Jahre alte Bautechnik mit nur einem einzigen Material. Länge (etwa 6 m) und Flexibilität sind wichtigste Eigenschaften des Materials.
FREIE DACHFORMEN		
Dachgrundriß: rechteckig		
Araber-Zelte, Beduinen, Berber, Tekna in der Arabischen Wüste und West-Sahara	Transportable Einfamilien-Unterkünfte mit Tragkonstruktion aus Vertikalstäben, manchmal gabelförmig, mit Firstpfetten oder geschnitzten Firststücken (gerundete Kappen als Stützabschluß). Darüber Dachhaut aus gewebtem Kamel- oder Ziegenhaar, mittels Seilen gespannt und im Boden durch Pflöcke oder Steine verankert.	Zeltgrößen je nach Tragkapazität des Familienkamels. Innere Vorhänge zur Aufteilung verschiedener Wohnbereiche, äußere Vorhänge verschiebbar, um Brisen einzufangen oder als Schutz vor Sandstürmen. Vollständige Schließung des Zelts möglich.

House Type, Tribe/Culture Country/Region	Materials and Constructions	Comments
Mudhifs of the Madan (Marsh Arabs) Southern Iraq	Bundled giant reeds, stuck in the ground and bent to form arches; roof covering of split reed mats.	6000 year old building technique, involving a single material. The length (about 6 meters) and flexibility are the main advantages of the material.
FREE FORMS		
Roof Base: rectangular		
Arab tents, Bedouin, Berber Tekna of the Arabian and Western Sahara deserts	Portable single family dwellings with supporting structure of vertical poles, sometimes forked, and ridgepoles or carved ridge pieces. The cover, woven from camel or goats' hair, is stretched over and held by long ropes, anchored with pegs or rocks.	Tent sizes are limited to the carrying capacity of the family camel. Interior curtains divide living spaces, exterior curtains may be moved from one side to the other for breeze or protection from sand storms. Complete closure of tent is also possible.

4.2 Neuentwicklungen

4.2.1 A.I.D.-Monsanto Forschungsprojekt für Low-Cost-Dächer

Das von der United States Agency for International Development, Washington D.C., unterstützte Forschungsprojekt wurde von der Monsanto Research Corporation, Dayton/Ohio, University of Washington, Seattle/Washington und Washington University, St. Louis/Missouri, von Mai 1973 bis Dezember 1977 durchgeführt.

Das Ziel war, Low-Cost Dachdeckungsmöglichkeiten aus einheimischen Materialien in drei Entwicklungsländern (Philippinen, Ghana und Jamaica) zu entwickeln, Dachprototypen (vier in jedem Land) zu montieren und zu testen und örtliche Fachleute und Firmen in die Forschungsarbeit einzubeziehen. Das Ziel, nur einheimische Materialien zu verwenden und den Devisenanteil zu vermindern, wurde später als weniger wichtig erachtet, als niedrigste Gesamtkosten für Bedachung zu erreichen.

Von etwa 50 erprobten Füllmaterialien wurde Bagasse (Zuckerrohrabfall) im Hinblick auf Produkteigenschaften, Kosten und Verfügbarkeit als das beste befunden. Als Bindemittel wurde aushärtendes Phenol-Formaldehydharz gewählt; gute Alternativen sind Naturkautschuk und ABS-Kunstharz. Vier Verbundplatten-Bedachungssysteme wurden entwickelt unter Verwendung hoher Prozentanteile von Bagasse und 5 bis 30% Bindemittel; die Kosten belaufen sich auf 0,7 bis 1,50 U.S.$/m^2. Es wurden wirtschaftliche Verfahren mit örtlich verfügbarem Gerät und Einrichtungen entwikkelt. Die Probeplatten waren entweder flach oder gewellt, aber bei den Musterdächern wurden hauptsächlich flache Schindeln verwendet.

Die Gesamtleistung der Mustereinheiten war gut, wenn man von kleineren Unzulänglichkeiten, wie Verwerfung der Schindeln, absieht. Aber alle Testdächer werden noch beobachtet, auch noch Beendigung des Projekts, um Daten über Langzeitverhalten zu erhalten. Weitere Entwicklungsarbeit wurde in den teilnehmenden Ländern empfohlen im Hinblick auf die Durchführung einer Massenfabrikation von äußerst stabilen, preiswerten, dauerhaften Dachplatten.

Quelle: "Development of low-cost roofing from indigenous materials in developing countries" (Contract No. AID/CM-ta-C-73-12)
Final Report, 20 February 1978
Monsanto Research Corporation, Dayton Laboratory, Dayton, Ohio 45407

4.2.2 Faserverstärkte Dachplatten

Zur leichten und schnellen Dachdeckung ist das beste Material große, dünne Platten, die eine größtmögliche Fläche bedecken bei kleinstmöglichem Volumen (daher leichter Transport). Weitverbreitete Dachplatten wie verzinktes Wellblech und Asbestzement sind für die meisten Eigenheimbauer in Entwicklungsländern zu teuer. Deshalb werden Versuche durchgeführt, Niedrigkosten-Dachplatten zu entwickeln, wo die Kostenverminderung entweder aus billigerem Material oder aus einfacher Herstellungsmethode (für Selbsthilfe geeignet) resultiert.

4.2 New Developments

4.2.1 A.I.D.-Monsanto Low-Cost Roof Research Project

The research project, sponsored by the United States Agency for International Development, Washington, D.C., was carried out by Monsanto Research Corporation, Dayton/Ohio, University of Washington, Seattle/Washington und Washington University, St. Louis/Missouri, between May 1973 and December 1977.

The aim was to develop low-cost roofing from indigenous materials in three developing nations (Philippines, Ghana and Jamaica), install and test prototype roofs (four in each country) and involve local experts and firms in the experimental work. The object of using only indigenous materials and minimizing the foreign exchange requirement was later regarded as being less important than achieving lowest total cost in roofing.

Of about 50 potential fillers tested, bagasse (sugar cane residue) was found to be best in terms of product properties, cost and availability. Phenol formaldehyde thermosetting resin was the selected binder, good alternatives being natural rubber and ABS thermoplastic resin. Four composite panel roofing material systems were developed which utilize major percentages of bagasse and 5 to 30% of binder, costing between 0.7 and 1.50 $ (U.S.)/m^2. Economical processes, using locally available equipment and facilities were developed. The test panels were either flat ar corrugated, but the demonstration roofs used mainly flat shingles.

The overall performance of the demonstration units was good, except for minor deficiencies, such as warping. But all test roofs are still being observed, even after termination of the project, in order to obtain long-term performance data. Further developmental work in the participating countries has been recommended, with a view to implementing large scale production of high-strength, low-cost, durable roofing panels.

4.2.2 Fibre Reinforced Roof Sheets

For easy and rapid installation of roofs, the most appropriate materials are large, thin sheets, which cover maximum area with minimum volume (hence ease of transport). Widely used sheets, such as corrugated galvanized iron and asbestos cement, are too expensive for most home builders in developing countries. Therefore attempts are being made to develop low-cost roof sheets, by which the cost reduction results either from the use of cheaper materials or from the simplicity of production (suitable for self-help).

Abb. 4.58 Herstellungsmethode von Welldachplatten aus faserverstärktem Zement (Intermediate Technology Building Materials/Parry and Ass. Ltd.)

Fig. 4.58 Method of making corrugated roof sheets of fibre reinforced cement (Intermediate Technology Building Materials/Parry and Ass. Ltd.)

Hier werden zwei Entwicklungen beschrieben: eine beruht auf dem Material-Aspekt, die andere auf der Methode. Beides sind Dachplatten aus Fasermaterial mit Zement als Bindemittel.

a. Elefantengrasfasern als Bewehrung in Dachplatten (untersucht von Professor T.S.R. Ayyar und P.K. Mirihagalla, School of Engineering, University of Zambia, Lusaka).

Elefantengras ist eine große, aufrechte, stämmige Pflanze, ähnlich wie Bambus, ca. 20 mm dick und über 2 m hoch. Die Fasern werden mittels einer Walzenquetsche gewonnen. Sie dienen als vollwertiger Ersatz für Asbest bei flachen Faserzementplatten oder als teilweiser Ersatz für Asbest bei Wellplatten. Elefantengrasfaser kostet ungefähr nur 20% der Kosten für Asbestfaser, aber bei der ersteren sind die Platten brüchiger und geringfügig weniger stabil. Es wird angenommen, daß Verbesserungen bei der Produktion möglich sind, aber die Erreichung von Asbestzement-Qualität scheint beim Niedrigkostenbau nicht erforderlich zu sein.
Verfahrensweise: Zement-Wasser-Verhältnis war 1 : 0,45. Die Streichmasse aus Zement und Fasern wurde in eine Standard-Gußform gegeben und mit einem Gewicht von 400 N mittels eines flachen Brettes zwei Stunden lang gepreßt; danach konnte sie sieben Tage lang aushärten. Sowohl flache als auch gewellte Platten wurden vorbereitet und getestet.

b. Handgefertigte Welldachplatten (entwickelt vom Intermediate Technology Building Materials Workshop, J.P.M. Parry and Associates Ltd., U.K.)

Die Platten können aus jeder geeigneten natürlichen oder synthetischen Faser hergestellt werden, mit Sand und gewöhnlichem Portland-Zement (1 Sack für 2,5 Platten von 2,5 m Länge). Die Preise für fabrikmäßig hergestellte Dachplatten sollen viel höher sein als die entsprechende Menge Zement, und zusätzliche Kostenminderung wird durch Selbsthilfe-Bauweise erreicht.
Verfahrensweise: Die Fasern müssen im allgemeinen auf die erforderlichen Längen beschnitten und die Knoten entfernt werden. Die Mischung aus Fasern und nassem Sand-Zementmörtel wird in einem einfachen Rahmen auf einer glatten geschmierten Platte ausgebreitet. Nach Glättung des Mörtels mit einer Kelle wird der Rahmen entfernt. Der Tisch wird danach gekippt und das flache Formbrett langsam herausgezogen, wobei der Mörtel die Form der darunterliegenden gewellten Unterlage annimmt. Die frisch geformte nasse Platte kann zwei Tage lang tracknen. Vor der Befestigung auf dem Dach ist eine weitere Aushärtung von einer Woche erforderlich.

Quellen: Appropriate Technology (erscheint vierteljährlich):
a. Vol. 6 Na. 1 (Mai 1979) - Elephant grass fibres
b. Vol. 5 No. 4 (Februar 1979) - Handmade roof sheets

Two developments are described here, one based on the material aspect and the other on the method. Both are roof sheets made of fibrous material, using cement as binder.

a. Elephant grass fibres as reinforcement in roof sheets (investigated by Professor T.S.R. Ayyar and P.K. Mirihagalla, School of Engineering, University of Zambia, Lusaka).

Elephant grass is a tall, erect, stout plant, similar to bamboo, about 20mm thick and more than 2 m high. The fibres have to be extracted in a roller crusher. They are used to completely substitute asbestos in flat fibre-cement sheets, or partially replace asbestos in corrugated sheets. Elephant grass fibre is estimated to cost only 20% of the cost of asbestos fibre, but the former produces sheets that are more brittle and have slightly lower strengths. It is assumed that improvements in production are possible, but the attainment of asbestos cement qualities does not seem necessary in low-cost constructions.

Process: Water-cement ration was 0.45. The slurry of cement and fibre was placed in a standard mould and compressed by a weight of 400 N applied through a flat slab for two hours, after which it was allowed to cure for seven days. Both flat and corrugated sheets were prepared and tested.

b. Handmade corrugated roof sheets (developed by Intermediate Technology Building Materials Workshop, J.P.M. Parry and Associates Ltd., U.K.)

The sheets can be made of any appropriate natural or synthetic fibres, with sand and ordinary Portland cement (one bag is needed for 2.5 sheets of 2.5 meters length). It is claimed that the prices of factory produced roof sheets are far higher than the equivalent amount of cement and additional cost reduction is achieved by self-help production.

Process: The fibres generally require trimming to appropriate lengths and removing of knots. The mixture of fibres and wet sand cement mortar is spread into a simple frame on a smooth lubricated sheet. After trowelling the mortar flat, the frame is removed. The table is then tilted and the flat bed slowly drawn out, allowing the mortar to take the shape of the corrugated former underneath. The wet sheet is allowed to cure on the former for two days. A further week's curing is necessary before installation on the roof.

4.2.3 Woudenberg Jute-Plastik, Bangladesh

Die Erfordernisse für ein neues Dachsystem in Bangladesh waren:

- Wirbelsturmresistenz und klimatisch angepaßte Bauweise,
- Verwendung von Jutefasern (wichtigstes Produkt des Landes),
- Einfachheit der Herstellung und Montage mit örtlich ausgebildeten Fachleuten,
- Niedrige Kosten und annehmbar für örtliche Bevölkerung.

Forschung und Produktion wurden in Bangladesh seit 1971 von William F. Woudenberg unter der Gönnerschaft und mit Unterstützung einer großen Anzahl von örtlichen und internationalen Organisationen einschließlich UNESCO, Weltbank und CARE, durchgeführt. Das Material, das sich als am geeignetsten herausstellte, war mit Jutefaser verstärktes Polyester, das beliebig geformt werden kann. So konnten große, leichtgewichtige, selbsttragende Dachelemente in einer örtlichen Werkstatt hergestellt und von zwei Männern leicht gehandhabt werden. Da sie auf jedem herkömmlichen Unterbau befestigt werden können, z.B. traditionelle Ziegelstein-Häuser, wurden die Elemente häufig benützt, um Gebäude zu decken, deren Dächer von Wirbelstürmen abgerissen wurden.

Diese Dächer wurden in erster Linie für Schulen und Kliniken entworfen, eignen sich jedoch ebenfalls für den Hausbau. Die Abbildungen zeigen nur einen Dachtyp aus einer großen Vielfalt von Entwurfsvarianten, von welchen einige ganze Häuser umfassen.

Der größte Nachteil des Materials ist, daß das Polyesterharz in Bangladesh nicht

Abb. 4.59 Fig. 4.59

4.2.3 Woudenberg Jute-Plastic, Bangladesh

The requirements for a new roofing system in Bangladesh were:

- cyclone resistance and climatic appropriateness,
- utilization of jute fibres (principal product of the country),
- simplicity of manufacture and assembly with locally-trained technicians,
- low-cost and good local acceptance.

Research and production was carried out in Bangladesh since 1971 by William F. Woudenberg, under the auspices and with the support of a wide range of local and international agencies including UNESCO, World Bank and CARE. The material that proved most suitable was jute-fibre-reinforced polyester, which could be moulded to any shape. Thus large lightweight, self-supporting roofing elements could be manufactured in a local workshop and easily handled by two men. Since they can be fixed on any traditional structure, eg. common brick-walled houses, the elements were widely used to cover buildings whose roofs were ripped off during cyclones.

These roofs were primarily designed for schools and clinics, but are equally suitable for housing. The illustrations show only one roof type out of a large variety of design solutions, some of which incorporating entire houses.

The major disadvantage of the material is that the polyester resin is not available in Bangladesh. It is, however, claimed that the resin can be imported cheaply from various countries with petro chemical industries.

Abb. 4.60 Fig. 4.60

verfügbar ist. Es wird jedoch behauptet, daß das Harz aus Ländern mit Petrochemie-Industrie billig importiert werden kann.

4.2.4 Ultra Low-Cost Housing für Bangladesh

Ein anderer Lösungsansatz für das Wohnungsproblem in Bangladesh wurde im Jahre 1974 - 75 durch die Carnegie Mellon University / INTERTECT Refugee Housing Team (Pittsburgh/Dallas) in einem Forschungsprojekt demonstriert, welches von der United States Agency for International Development finanziert wurde.

Die Flüchtlingsunterkunft, die für bessere Windbeständigkeit stromlinienförmig konzipiert ist, kann komplett aus lokalen Materialien mit traditionellen Bautechniken gebaut werden. Die tragenden Bauteile der A-Rahmen können aus Holz oder Bambus sein. Die vertikalen und horizontalen Abmessungen können variiert werden, ebenso wie die Dachdeckungsmaterialien (Strohschindeln, Matten, geflochtener Bambus), die durch andere geeignete Materialien ohne wesentliche Entwurfsabänderungen ersetzt werden können. Eine Lüftungsmöglichkeit ist in der Firstlinie vorgesehen, und Fenster können beliebig angeordnet werden.

Der größte Nachteil der A-Rahmen ist die an den Seiten verlorengehende Nutzfläche, was bei kleinen Gebäuden wesentlich ist. Aber abgesehen davon wurden die Bauten von der örtlichen Bevölkerung gut aufgenommen.

Quellen: "Feasibility Test of an Approach and Prototype for Ultra Low Cost Housing" Schlußbericht (1975) und Evaluierungsbericht (1977) von C.G. Goodspeed, V.H. Hartkopf, F.C. Cuny, V.P. Singh von der Interdisciplinary Working Party, Carnegie Mellon University, Pittsburgh, Pennsylvania 15213.

4.2.4 Ultra Low-Cost Housing for Bangladesh

Another approach to the housing problem in Bangladesh was demonstrated in 1974 - 75 by the Carnegie Mellon University/INTERTECT Refugee Housing Team (Pittsburgh/Dallas) in a research project, funded by the United States Agency for International Development.

The refugee shelter, which is streamlined for better wind performance, can be built entirely of local materials, employing traditional building techniques. The structural members of the A-frames can be timber or bamboo. Vertical and horizontal dimensions are variable, just as the roofing materials (thatch shingles, mats, woven bamboo), which can be replaced by other appropriate materials without major design modifications. A means of venting is devised at the vertex and windows can be provided where needed.

The major disadvantage of the A-frames is the floor space lost at the sides, which is significant in small buildings. But apart from this, the structures found good acceptance by the local people.

4.2.5 In Indien entwickelte Dachelemente

Von der großen Anzahl der am Central Building Research Institute, Roorkee, entwickelten Dachelemente werden hier drei Typen beschrieben.

a. Doppelt gekrümmte Dachplatten.
Die Plattenherstellung erfolgt in einfachen Holzrahmen, 70 x 70 cm, die mit Sackmaterial bespannt sind und mittels Nägeln straff gehalten werden. Der Rahmen liegt auf einem flachen Untergrund und wird 2 cm hoch mit Beton gefüllt, dann hochgehoben, so daß das Tuch unter dem Gewicht des Betons absackt und so die doppelt gekrümmte Dachplatte bildet. 8 bis 10 Dachplatten, die 24 Stunden lang getrocknet werden, dienen als Grundformen zur Herstellung weiterer Dachplatten. Plastikplanen oder Ölpapier, das man darauflegt, ergibt eine glatte Oberfläche und verhindert, daß die frischen Ziegel an den Formen ankleben. Die fertigen Dachplatten werden 24 Stunden getrocknet, 7 Tage lang in Wasser ausgehärtet und zur vollstän-

4.2.5 Roofing Elements Developed in India

Of a large number of concrete roof elements developed at the Central Building Research Institute, Roorkee, three types are described here.

a. Doubly curved tile roof.
The tiles are made in simple wooden frames, 70 x 70 cm, mounted with hessian cloth, held taut by nails. The frame lying on a flat surface is filled with concrete 2 cm thick and then lifted, so that the cloth sags under the weight of the concrete, forming the doubly curved tile. 8 to 10 tiles, dried for 24 hours, serve as base moulds for casting more tiles. Polythene sheets or oiled paper laid on top provide a smooth surface to prevent fresh tiles from sticking to the moulds. The finished tiles are dried for 24 hours, cured in water for 7 days and stored for 15 days to allow completion of drying shrinkage. Simple prefabricated beams are also made and installed at 76 cm distances to support the tiles. The gaps are filled with cement concrete,

digen Trockenschrumpfung 15 Tage lang gelagert. Einfache Balken werden auch vorgefertigt und in 76 cm-Abständen montiert, um die Dachplatten zu tragen. Die Lücken werden mit Zementbeton gefüllt, während die Wasserfestigkeit und der Oberflächenabschluß mittels Kalkbeton, der mit Tonfliesen bedeckt ist, erreicht wird.

b. Trogelemente.
Die Form für diese selbsttragenden Elemente ist nicht so einfach wie die vorhergehende, aber die Installierung auf der Baustelle ist leicht. Sie sind im Querschnitt trogförmig, die Seiten gewellt und an den Enden gerillt, um so die Lasten seitlich zu übertragen. Die Nennweiten sind 300 oder 600 mm, Tiefe 130 mm, während die Längen zwischen 2,5 und 4,2 m variieren können. Sie brauchen während der Bauzeit keine temporäre Unterstützung und benötigen keine Betonüberdeckung.

c. L-Pan-Dachdeckung.
Die Paneele werden auf der Baustelle in einfachen Formen gegossen, das Zusammenfügen des Daches ist ebenso einfach (Ortbeton wird nur bei Verbindungsfugen benötigt). Diese vorgefertigten Paneele mit L-förmigem Querschnitt werden für geneigte Dächer verwendet. Sie werden an parallelen Giebelwänden oder Bindern aufgesetzt und überlappen die angrenzenden darunterliegenden Paneele. Eine angemessene Paneelgröße könnte 300 x 48 x 12 cm sein, 4 cm dick, obwohl die Abmessungen verschiedenen Gebäudegrößen angepaßt werden können.

Quellen: Building Digest 43 (1966): Doubly curved tile roof
Data Sheet — Building Technical Series 5 (1977): Channel Units
Data Sheet — Building Technical Series 10 (1978): L-Pan roofing
sämtlich vom Central Building Research Institute, Roorkee, Indien.

while waterproofing and surface finish is provided by lime concrete covered with clay tiles.

b. Channel units.
The mould for these self-supporting units is not as simple as the previous one, but installation on the building is easy. They are trough-shaped in section, the sides are corrugated and grooved at the ends, to help transferring the loads transversely. Nominal widths are 300 or 600 mm and depths 130 mm, while lengths can vary between 2.5 and 4.2 m. They do not require any type of temporary support during construction and need no deck concrete.

c. L-Pan roofing.
Casting of panels is done on the site in simple moulds, assembly of the roof is equally easy (insitu concrete is only needed at junctions). These precast panels with L-shaped sections are used for sloping roofs. They are supported on parallel gable walls or trusses and overlap the adjacent lower panels. A suitable panel size could be 300 x 48 x 12 cm, 4 cm thick, though dimensions are adaptable to various building sizes.

4.2.6 In Südafrika entwickeltes Dachdeckungselement

Ein trogförmiges vorgefertigtes Betondachelement wurde am National Building Research Institute, Pretoria, für ein Prototyp-Haus entwickelt. Das trogförmige Profil ermöglicht das Stapeln während der Herstellung. Das Dach wurde mit Plastikfolie auf den Betonelementen wasserdicht gemacht. Diese wurde mit einer lockeren Kiesschicht bedeckt, die die thermischen Eigenschaften des Daches beträchtlich verbessert. Der Kies wird von geformten, vorgefertigten Einkornbetonblöcken, die in den Trögen als Randabschluß liegen, festgehalten. Das Regenwasser sickert durch den Einkornbeton zur Dachrinne.

National Building Research Institute, Pretoria, Südafrika.

4.2.6 Roofing Element Developed in South Africa

A trough shaped prefabricated concrete roof element was developed at the National Building Research Institute, Pretoria for a prototype house. The trough-shaped profile allows for stacking during the casting operation. The roof was waterproofed with plastic sheeting placed on top of the concrete elements. This was covered with a layer of loose gravel that greatly improves the thermal performance of the roof. The loose gravel is kept in place by shaped, precast, no-fines concrete blocks placed in the roof troughs at the verges. The rainwater percolates through the no-fines concrete to the gutter.

National Building Research Institute, Pretoria, South Africa.

4.2.7 Ecol House, Canada.

Das "Ecol Operation" genannte Projekt, 1972 von der Minimum Cost Housing Group, Mc Gill University, Montreal, unternommen, umfaßte eine Anzahl von Bauneuerungen zum Zwecke der Kostenreduzierung und zur Vereinfachung von Baumethoden. Eine Erfordernis war es, ein einfaches, selbsttragendes Dach mit einer Spannweite von 3,60 m zu errichten. Eine Lösung, ähnlich der Asbestzement-Trogplattendächer (canaletas), die in lateinamerikanischen Ländern gebräuchlich sind, wurde gesucht, und eine billige Alternative wurde gefunden, indem man Asbestzemententwässerungsrohre der Länge nach in vier Teile schnitt und sie wie herkömmliche Mönch- und Nonnen-Ziegel verlegte. Pro Schnitt wurden für 25 mm dicke Rohre drei Stunden gerechnet, aber der Vorgang wurde dadurch vereinfacht und beschleunigt, daß man nur 6 mm tief schnitt, so daß das Rohr bei geringem Anheben und Fallenlassen entlang der Schnittliene brach. Ergebnis: vier Schnitte in der Stunde.

Quelle: "The Ecol Operation" von der Minimum Cost Housing Group, Mc Gill University, Montreal, Canada, 1972

4.2.7 Ecol House, Canada

The project, called the Ecol Operation, undertaken in 1972 by the Minimum Cost Housing Group, McGill University, Montreal, incorporated a number of building innovations, designed to reduce costs and simplify construction methods. One requirement was to erect a simple, self-supporting roof to span 3.60 m. A solution, corresponding to asbestos cement channel roofs (canaletas) common in Latin American countries, was sought and an appropriate, cheap alternative was found by cutting asbestos cement sewer pipes lengthwise in four parts and assembling them like traditional Spanish roof tiles. Cutting the 25 mm thick pipes was found to take three hours per cut, but the process was simplified and accelerated by cutting only 6 mm deep, so that when slightly raised and dropped, the pipe split along the score-line. Result: four cuts per hour.

4.2.8 Bambus-Polyurethan-Dachkonstruktion, Peru

Diese Dachlösung wurde von Christopher Alexander für eine low-cost-housing-Siedlung entworfen (Proyecto Experimental de Vivienda, internationaler Wettbewerb, ausgeschrieben von den Vereinten Nationen, der peruanischen Regierung und der Housing Bank, 1969). Es umfaßt ein System von Balken und Bohlen, die aus einem Polyurethan-Schaumstoffkern mit darumgebundenen Bambusrohren bestehen. Zur Verbindung, und um eine wasserdichte Begehungsfläche zu erhalten, erhalten die Planken eine Deckschicht aus einer flüssigen Schwefel-Sand-Mischung. Dies wurde in den Vereinigten Staaten umfassend getestet. Die Elemente sind leichtgewichtig, leicht zu handhaben und zu montieren, der Schaumstoffkern verleiht ausgezeichnete klimatische und akustische Bedingungen.

Quelle: "Houses Generated by Patterns" by C. Alexander, et al.
Center for Environmental Structure, Berkeley, California, 1969

4.2.9 Kokospalmdächer, Philippinen

Die Dachkonstruktion, die von Ian Athfield, Neuseeland (in seinem 1. Preis-Entwurf für den internationalen Wettbewerb für einen Stadtteil von Manila, 1975) vorgeschlagen wurde, basiert auf der Kokospalme und deren Nebenprodukten. Das Holz kann in seinem natürlichen Zustand verwendet werden, wenn es getrocknet und konserviert wird. Ganze, halbe oder geschnittene Kokosstämme wurden für den Dachrahmen vorgeschlagen. Die Dachdeckung bestand aus Kokospreßspanplatte an der Unterseite, einer Isolierschicht aus Kokos-Faser-Zement und einem mit Maschendraht bewehrten Außenputz aus Kokossägemehl, Sand und Zement.

Quelle: Architectural Record (Mai 1976), eine McGraw-Hill Veröffentlichung, New York.

4.2.8 Bamboo-Polyurethane Roof Structure, Peru

This is a roofing solution designed by Christopher Alexander for a low-cost housing scheme in Peru (Proyecto Experimental de Vivienda, international competition sponsored by the United Nations, Peruvian Government and Housing Bank, 1969). It comprises a system of beams and planks, all made of whole bamboo culms bound together around a polyurethane foam core. For jointing and to provide a waterproof walking surface, the planks receive a topping of molten sulphur mixed with sand. These have been widely built and tested in the United States. The elements are light, easy to handle and install, the urethane core giving excellent thermal and acoustical performance.

Source: "Houses Generated by Patterns" by C. Alexander, et al.
Center for Environmental Structure, Berkeley, California, 1969

4.2.9 Coconut Palm Roofs, Philippines

The roof construction, suggested by Ian Athfield, New Zealand (in his first-prize-winning design for the international competition for an urban environment in Manila, 1975), is based on the coconut palm and its by-products. The timber can be used in its natural state if dried and preserved. Whole, half or cut coconut logs were proposed for the roof frame. The roof cover consisted of coconut particle board on the underside, an insulation layer of coconut-fibre-cement and an exterior plaster with coconut sawdust, sand and cement over expanded wire mesh.

4.2.10 Hängedachsystem, Korea

Als Teil eines Forschungsprojektes, das an der Yeungnam Universität, Taegu, Korea, 1973 unternommen wurde, wurde dieser Dachtyp in erster Linie für Bauern- und Fischerdörfer entwickelt. Das System umfaßt Holzteile für First, Traufe und Zugbalken, während die Dachsparren von Stahlseilen, die in 1 m Abständen verlaufen, ersetzt werden. Eine Sperrholzdecke wird mittels Drahtseilen abgehängt. Holzpfetten werden durch Maschendraht ersetzt, der das Dach aus wasserdichten Polyäthylen-Folien, Strohmatten, Erde und Dachziegeln trägt. Die Hauptvorteile dieses Systems sind einfache Konstruktion und eine Kostenverringerung von ca. 35% im Vergleich zu herkömmlichen Systemen.

Quelle: "Low-Cost Housing for Agro-Fishery Villages in Korea" von Sun-Ho Choi, veröffentlicht in Proceedings of Adaptive Technology Workshop II, 1973, East-West Center, Honolulu, Hawaii.

4.2.10 Suspension Type Roof System, Korea

As part of a research project, undertaken at Yeungnam University, Taegu, Korea, in 1973, this roof type was developed primarily for agro-fishery villages. The system comprises timber members for ridge, eaves and tie beams, while the rafters are substituted by wire ropes spaced 1 m apart. A plywood ceiling is suspended from the wire ropes. Timber purlins are substituted with wire mesh, which is overlaid by waterproofing polyethylene sheets, straw matting, seating soil and roof tiles. The main advantages of this system are simple construction and cost reduction of about 35% as compared to conventional systems.

4.2.11 Versuchsbauten der Gesamthochschule Kassel, Bundesrepublik Deutschland

Die nachstehend beschriebenen Bauten wurden am Forschungslabor für Experimentelles Bauen, Gesamthochschule Kassel, unter der Leitung von Gernot Minke, entwickelt. Die Hauptziele der Forschungsarbeit, die 1974 begann, waren, neue Materialien und Methoden zur Low-Cost-Bauweise zu entwickeln bzw. bestehende Technologien zu verbessern. Das Resultat waren eine Anzahl interessanter Lösungen.

4.2.11 Experimental Structures of University Kassel, Germany

The structures described below were developed at the Laboratory for Experimental Construction, Kassel University, under the guidance of Gernot Minke. The prime objectives of the research work, which began in 1974, was to develop new materials and methods for low-cost construction or improve on existing technologies. This resulted in a number of interesting solutions.

a. Schwefel-Beton-Haus.
Das Rotationsparaboloid wurde aus einer Mischung von geschmolzenem Schwefel, Kies und Sägemehl hergestellt. Der Testkörper wurde mit Hilfe einer besonderen, eigens dazu entwickelten Rotationsgleitschalung gegossen. Diese Form, welche Genauigkeit garantierte und die Arbeit auf drei Personen reduzierte, wurde wegen der raschen Härtung des heißen Schwefels klein gehalten (20 x 40 cm). Das Hauptproblem ist die Entwicklung einer einfachen Vorrichtung, um den Schwefel in flüssigem Zustand zu halten. Drei Maschinen wurden entwickelt und getestet. Ein Vorteil des Materials ist, daß es abgebrochen und in der gleichen Weise wie vorher ohne Masseverluste wiederverwendet werden kann. Außerdem sind die benützten Materialien im allgemeinen billiges Abfallmaterial.

b. Vorgefertigtes Paneelhaus.
Die Wände und das Dach des abgestumpften Hexaoktaeders bestanden aus 13 quadratischen und 4 dreieckigen Paneelen, und zwar Holzrahmen mit verschiedenen Ausfachungen: mit Schwefel- oder Polyesterharz getränkten Glasfiber- oder Jutefaser (Abfall!)-Bespannungen, die mit Ausnahme der Dreiecks-(Licht)elemente mit einer schwefelgebundenen Blähtonschicht versehen wurden. Das Ziel war, diese Materialien in verschiedenen Zusammenstellungen zu testen.

c. "Bio-Bau".
Das Testgebäude mit parabelförmigem Querschnitt und drei halben Rotationsparaboloiden bestand aus Holzrippen- und -gitterschalen, die mit aluminiumverstärkten Polyäthylen-Folien (Abfall aus der chemischen Industrie) bedeckt waren, auf welchen erdgefüllte Säcke mit Pflanzen schuppenartig be-

a. Sulphur-concrete house.
The rotational paraboloid structure was made of a mixture of molten sulphur, gravel and sawdust, poured in a special rotating-sliding formwork. This formwork, which ensured accuracy and reduced labour to three persons, was kept small (20 x 40 cm) because of the rapid hardening of hot sulphur. The major problem is the development of a simple device for keeping the sulphur in the molten state for pouring. Three machines were developed and tested. An advantage of the material is that it can be demolished and reused in the same way as before, without volumetric loss. Besides, the materials used are generally cheap waste materials.

b. Prefabricated panel house.
On an octahedronal plan, the walls and roof were made of 13 square and 4 triangular panels, which were timber frames with varying infills: fibreglass or jute fibre (waste!) reinforcements with sulphur or polyester resin covered with sulphur-bonded expanded clay. The object was to test these materials in different combinations.

c. "Bio-building".
The test structure, with parabolic cross-section and three half rotational paraboloids, consisted of a wooden framework covered with aluminium reinforced polyethylene sheets (waste from chemical industry), on which soil filled sacks carrying plants were placed like shingles. Three types of soil and 17 different plant groups were tested. The aim of the project was to test simple, low-cost prefabrication and construction methods, using environmentally and structurally appropriate materials. New plant systems will be tried out from time to time.

Fig. 4.80 Sand-sack house

festigt wurden. Drei verschiedene Grundsubstrate und 17 verschiedene Pflanzengesellschaften wurden getestet. Das Ziel des Projekts war, einfache vorgefertigte Billigbauweisen unter Verwendung umwelt- und konstruktionsgerechter Materialien zu testen. Neue Pflanzsysteme werden von Zeit zu Zeit ausprobiert.

d. Sandsack-Haus.
Schlauchförmige Säcke, insgesamt 220 m lang, gefüllt mit Sand (für den unteren Teil des Gebäudes) und Blähton (für den oberen Teil) waren die hauptsächlich angewandten Materialien. Die Schläuche wurden ringförmig aufeinandergelegt, so daß der Querschnitt des Baukörpers der Form einer umgekehrten Kettenlinie entsprach, um Zugkräfte innerhalb des Wandquerschnitts auszuschalten. So wirkte jede Lage als Druckring.

e. Pappkarton-Haus.
Auf einer Unterkonstruktion aus halbkreisförmigen Holzbindern und Pfetten wurden wetterfeste Papptafeln befestigt. Die 8 mm dicke Pappe, die mit dem Secor-Verfahren im Vakuum imprägniert wurde, bestand aus zweilagiger Wellpappe mit drei Lagen 400 g-Karton. Bei der Befestigung auf der Unterkonstruktion wurden die einzelnen Pappen durch eine spezielle Falztechnik so miteinander verbunden, daß keine Abdichtungsmaßnahmen erforderlich waren und keine offenen Schnittkanten auftraten. Regen und Schnee weichten das Pappmaterial etwas auf und ließen es nur geringfügig auf-

d. Sand-sack house.
Tubular sacks, totalling 220 m, filled with sand (for lower part of building) and expanded clay (for upper portion) were the principal materials used. These were laid in circles on top of each other, forming a round building with an inverted chain-line (catinery) cross-section, to eliminate tensile forces. Thus each layer acted as a compression ring.

e. Paperboard house.
On a wooden vault-shaped framework impregnated corrugated paperboards were fixed. The 8 mm thick boards, vacuum impregnated by the Secor process, had two corrugations and three layers of 400 g carton. The attachment to the substructure incorporated special folding techniques to avoid open cut edges. Rain and snow caused only slight softening and swelling of covering material, but returned to normal after drying. Bitumen felts would have been more resistant but also more expensive. The paperboard house has a life-span of 3 to 5 years, depending on the climatic conditions to which it is exposed.

f. House from waste consumer packaging.
The walls and roof of the 19 m^2 house were made of sandwich elements, i.e. discarded cans or bottles, stuck together with bitumen, with corrugated paperboard (as used in previous structure) on either side. This system, which is only relevant for countries producing this kind of waste in abund-

quellen, es erhielt jedoch nach dem Trocknen wieder seinen Normalzustand. Bitumenpappe wäre widerstandsfähiger, aber auch viel teurer gewesen. Das Pappkarton-Haus hat eine Lebensdauer von 3 bis 5 Jahren, je nach den klimatischen Gegebenheiten.

f. Haus aus Abfall-Verpackungsmaterial.
Die Wände und das Dach des 19 m^2 großen Versuchsbaus bestanden aus Sandwich-Elementen, d.h. Einwegdosen und -flaschen, die mit Bitumen verklebt und beidseitig mit wetterfester Wellpappe (wie bei der vorhergehenden Konstruktion) versehen wurden. Dieses System, welches nur in denjenigen Ländern sinnvoll ist, die derartige Abfallprodukte in Mengen zur Verfügung haben, kann so extrem billige, ziemlich dauerhafte Konstruktionen ermöglichen und gleichzeitig zur Lösung eines gravierenden Abfallproblems beitragen.

g. Grasdach.
Ein Dachtyp, der traditionell sowohl in heißen als auch in kalten Regionen verwendet wird, wurde ebenfalls getestet. Das Dach besteht aus einer herkömmlichen Rundholzunterkonstruktion und wasserdichtem, PVC-beschichtetem Polyestergewebe, auf welches 8 - 10 cm dicke Grassoden gelegt wurden. Das Dach wurde so belassen, daß sich natürlicher Pflanzenwuchs entsprechend seinem eigenen ökologischen System entwickeln kann. Die Vorteile

Abb. 4.81 Pappkarton-Haus
Fig. 4.81 Paperboard house

ance, can thus provide extremely cheap, reasonably durable constructions and also help to solve a major disposal problem.

g. Grass roof.
A roof type traditionally used in both hot and cold regions was also tested. The roof substructure consists of a conventional roundwood framework and impermeable PVC-coated fabric, on which 8 - 10 cm thick sod pieces were laid. The roof was left to develop plant cultures naturally, according to its own ecological system. The advantages of grass roofs are:
- regulating effect on temperature fluctuations; temperatures of corrugated iron roofs can range periodically about 100°C, while grass roofs rarely exceed 30°C; during daytime cooling effect due to evaporation and consumption of heat by photosynthesis and warming effect by respiration process;
- heat retaining capacities of soil and water content, as well as heat insulation through air spaces in soil and between grass blades, thus suitable for almost any climate;
- no special maintenance.

Abb. 4.82 Haus aus Abfall-Verpackungsmaterial
Fig. 4.82 House from waste consumer packaging

der Grasdächer sind:
- Ausgleichende Wirkung bei Temperaturschwankungen; die Temperaturen von Wellblechdächern können zeitweise ca. 100°C betragen, während Grasdächer sich kaum über 30°C erwärmen; während der Tageszeit Kühlungseffekt aufgrund von Verdunstung und Wärmeverbrauch durch Photosynthese, und während der Nacht Wärmeeffekt durch den Atmungsprozeß.
- Wärmespeicherfähigkeit der Erde und des darin enthaltenen Wassers sowie Wärmeisolierung durch Lufträume in der Erde und zwischen Grashalmen, und somit für fast jedes Klima geeignet.
- Keine besondere Wartung.

4.2.12 Schaumstoff-Iglus

Das System, welches vom deutschen Chemiewerk Bayer Leverkusen entwickelt wurde, bestand im Prinzip aus dem Aufblasen einer Ballonschalung, auf welche fester Moltoprenschaum aufgespritzt wurde, der 30 Minuten härtete; danach wurde der Ballon abgeblasen. Türen und Fenster konnten mit einer Säge leicht ausgeschnitten werden. Die ganze Behausung konnte von 10 - 15 Männern getragen werden.

Diese schnell-errichteten Billigbauten waren erdbebensicher und daher in erster Linie als Notbehausungen nach Erdbeben in der Türkei, in Peru und Nicaragua in den frühen 70er Jahren verwendet. Sie werden jedoch aus folgenden Gründen nicht mehr gebaut:

- Lüftung war schlecht, die Kuppeln waren im Sommer unerträglich heiß;
- der halbkugelförmige Baukörper verursachte Möblierungsprobleme und die Akustik war äußerst nachteilig;
- beschädigter Schaumstoff konnte nicht repariert werden, zerbrochene Stücke konnte man nicht wiederverwenden; im Sommer verursachte er üble Gerüche, und wenn die Schutzschicht abgewaschen war, nisteten Insekten darin.

Quellen: Informationsblatt von Bayer Leverkusen, 1971
Shelter II, Shelter Publications, Bolinas, California 1978

4.2.12 Foam Igloos

The system developed by the German chemical firm Bayer Leverkusen, basically consisted of blowing up a balloon-mould onto which rigid moltoprene foam was sprayed, allowing it to harden for 30 minutes, after which the balloon was deflated. Doors and windows were easily cut out by means of a saw. The whole dwelling could be carried by 10 - 15 men.

These quickly erected low-cost structures were earthquake resistant and hence used primarily as emergency housing units after earthquakes in Turkey, Peru and Nicaragua in the early 1970s. However, they are not being built any more for the following reasons:

- ventilation was poor, the domes were insufferably hot in summer;
- the hemispherical shape created difficulties in furnishing, and interior acoustics proved extremely disadvantageous;
- damaged foam could not be repaired, broken pieces were not reusable; in summer it exuded bad smells and, when the protective coat was washed off, harboured insects.

4.2.13 Membran-Konstruktionen, Bundesrepublik Deutschland

In einer Studie über Dachdeckungssysteme dürfen Membran-Konstruktionen nicht fehlen. Es sind leichtgewichtige Zelt- oder pneumatische Konstruktionen, die für Räume von fast unbegrenzten Formen und Größen geeignet sind. Sie basieren auf den Zugbeanspruchungs-Eigenschaften der verwendeten Membranen, Kabel und Netze. Konstruktionen dieser Art werden primär mit dem Namen Frei Otto in Verbindung gebracht, der das Institut für leichte Flächentragwerke an der Technischen Universität Stuttgart gründete, und der seit 1955 mit Forschungs- und Entwicklungsarbeiten Pionierleistungen vollbrachte. Die meisten seiner Entwicklungen sind Großprojekte; bis jetzt wurden sie im Niedrigkosten-Wohnungsbau nicht angewendet.
Sein früherer Mitarbeiter, Gernot Minke, hat jedoch Forschungsarbeiten über aufblasbare Konstruktionen durchgeführt und ihre Verwendbarkeit im Billigbau studiert, kam jedoch zu dem Schluß, daß deren Anwendung im Wohnungsbau sehr begrenzt ist. Da dies ein relativ neues Gebiet ist, ist es trotzdem wahrscheinlich, daß Lösungen für den Billigwohnungsbau — sogar für Entwicklungsländer in tropischen Gebieten — zu einem späteren Zeitpunkt aus der weiteren Forschung über leichte Flächentragwerke resultieren können.

Institut für leichte Flächentragwerke, Universität Stuttgart.
"Light-Weight Structures for Self-Help, Low-Cost Housing Systems"
von Gernot Minke. Vortrag beim 3. Internationalen Symposium über Low-Cost Housing-Probleme 1974 in Montreal, Canada.

4.2.13 Membrane Structures, Germany

In a study on roofing systems, membrane structures cannot be omitted. These are lightweight tent or pneumatic structures, suitable for enclosing spaces of almost unlimited shapes and sizes. They are based on the tensile properties of the membranes, cables and nets used. Structures of this nature are primarily associated with the name of Frei Otto, who founded the Institute for Lightweight Structures at the Technical University Stuttgart, and who has been involved in pioneering research and development since 1955. Most of his developments are large-scale projects, there have been no applications in low-cost housing schemes so far.

His former colleague, Gernot Minke, has however, carried out experimental work on pneumatic structures and studied their appropriateness for low-cost housing, but came to the conclusion that they have very limited application for housing. Nevertheless, since this is a relatively new field, it is likely that solutions for low-cost housing — even for developing countries in tropical areas — may at a later date be derived from further research on tensile structures.

Abb. 4.87 Gewölbe mit zwei Halbkuppeln (V. Sedlak)

Fig. 4.87 Vault closed with two semi-domes (V. Sedlak)

4.2.14 Faltwerk-Bauten, Großbritannien

Forschung und Entwicklung dieser kostengünstigen Gebäudehüllen wurde von Vinzenz Sedlak an der Universität Surrey, Guildford, durchgeführt. Faltsysteme können eine große Vielfalt von komplexen selbsttragenden, lastentragenden Konstruktionen erzeugen, nur durch Zusammensetzung einer kleinen Anzahl von verschiedenen flachen, dreieckigen Elementen mit geringem Elastizitätsmodul. Sie sind für die Vorfertigung bestens geeignet und können extrem biegungs- und torsionssteif sein, weshalb sie erdbebensicher sind (Notbehausungen!). Ihr Verhalten bei Stürmen ist nicht bekannt. Sie können äußerst leichtgewichtig sein, zusammenfaltbar zur leichten Handhabung bei Transport und Aufbau, und sind zum "do-it-yourself"-Bau durch ungelernte Benutzer geeignet.

Quellen: "Paper Shelters", Artikel in Architectural Design (Dez. 1973);
"Folded Structural Forms — Their Geometry and Architectural Applications", Vortrag beim 3. Internationalen Symposium über Lower Cost Housing Problems 1974 in Montreal, Canada, beide von Vinzenz Sedlak.

4.2.14 Folded Surface Structures, United Kingdom

Research and development of these lower cost building enclosures was conducted by Vinzenz Sedlak at the University of Surrey, Guildford. Folded systems can create a large variety of complex self-supporting, load-bearing structures, only by assembling a small number of different plane triangular surface elements having low modulus of elasticity. They are ideally suited for prefabrication and can possess considerable stiffness and torsion resistance, making them safe in earthquakes (emergency housing!). Their performance in strong winds is not known. They can be extremely lightweight, collapsible for easy handling during transport and erection, allowing "do-it-yourself" construction by unskilled users.

Sources: "Paper Shelters", article in Architectural Design (December 1973);
"Folded Structural Forms — Their Geometry and Architectural Applications", paper delivered at the 3rd International Symposium on Lower Cost Housing Problems, 1974 in Montreal, Canada, both by Vinzenz Sedlak.

4.2.15 Abfalldächer, USA

Auf der Suche nach alternativen Lebensformen als Antwort auf die gegenwärtige Konsumgesellschaft haben Gruppen junger Leute in den letzten Jahren verschiedene Typen von "do-it-yourself"-Behausungen entwickelt, wovon viele von Abfallmaterialien Gebrauch machten. Drei Beispiele hierfür sind:

Drop City
Bei diesen Kuppelkonstruktionen, in willkürlicher Anordnung — wie Tropfen (Drops) — auf einer Ziegenweide in Süd-Colorado aufgebaut, wurden Abfallmaterialien von den verlassenen Häusern in der Umgebung benützt. Die Außenhaut der abgebildeten Kuppeln besteht aus Autodächern, die mit Äxten auf die benötigten Formen und Größen zugeschnitten wurden. Die Bleche, die billig und stark sind und ausgezeichneten Oberflächenschutz bieten, wurden mit Nägeln, Schrauben oder durch Zusammenschweißen einzelner Stücke an den Holzrahmen befestigt.

4.2.15 Garbage Roofing, U.S.A.

Groups of young people in search of alternative life-styles as an answer to present day consumer societies, have in recent years developed various types of "do-it-yourself" dwellings, many of which make use of waste materials. Three examples are:

Abfalldächer, USA
Garbage Roofing, USA
Abb. / Fig. 4.88 — 4.90
aus / from : Wolfgang M. Ebert, "Home Sweet Dome" (1978)

Abb. 4.88 Drop City
Fig. 4.88 Drop City

Einwegdosen-Haus

Aus der Tatsache heraus, daß die Menge von weggeworfenen Büchsen und Flaschen die Produktion von Ziegel- und Betonmaterialien um das Sechsfache übersteigt, werden Versuche unternommen, sie zum Bauen zu verwenden. Das abgebildete runde Haus ist ein Beispiel, das aus ungefähr 75.000 Einwegdosen hergestellt wurde. Andere benützen leere Flaschen, die auch zum Teil die Fenster ersetzen. In einigen Fällen werden die Büchsen mit Wasser gefüllt, so daß sie während des Tages Sonnenwärme speichern und diese Wärme bei Nacht abgeben.

Freie Form

Auf einem unfruchtbaren Stück Land in Neu-Mexiko errichtet, wurde diese zeltartige Konstruktion aus Bauschutt einer nahegelegenen Geisterstadt gebaut. Vorher wurden keine Pläne gemacht, die Form entwickelte sich aus den verwendeten Materialien. Aber ironischerweise wurde das Haus verlassen, nachdem es fertiggestellt war, und ist nun ein Abfallhaufen in der Wüste.

Quellen: "Home Sweet Dome" von Wolfgang Ebert, Verlag Dieter Fricke GmbH., Frankfurt/Main (1978)
"Shelter and Society", herausgegeben von Paul Oliver, Barrie + Rockliff: The Cresset Press, London (1969)
"Shelter", Shelter Publications, Bolinas, California (1973)

Drop City

These dome-structures, built at random — like drops — on a goat pasture in southern Colorado, made use of waste materials from abandoned buildings in the area. The domes illustrated were covered with car tops, cut to required shapes and sizes with axes. The sheets, which are cheap, strong and have excellent surface protection, were attached to the wooden frame by nails, screws or even by welding pieces together.

Tin Can House

Arising from the fact that the volume of discarded cans and bottles exceeds the production of brick and concrete materials by six times, attempts are made to use them for building. The illustrated round house is an example made of about 75.000 cans. Others use empty bottles, which also partially substitute windows. In some cases, cans are filled with water, so that they accumulate heat by solar radiation during the day and thus provide heating during the night.

Free Form

Erected on a barren piece of land in New Mexico, this tent-like structure was built of waste building materials from a nearby ghost-town. No plans were made beforehand, the form developed out of the materials used. But ironically, this building itself was abandoned after it was finished and is now a heap of waste in the desert.

5. DÄCHER IN ZENTRALAMERIKA +

5.1 Allgemeines

5.1.1 Topographie, Klima und Naturereignisse

Geographisch erstreckt sich der zentralamerikanische Isthmus vom Tehuantepec Isthmus in Mexiko bis zum Atrato-Tiefland in Kolumbien; für die vorliegende Studie wurden jedoch nur die fünf Länder in Betracht gezogen, welche die Zentralamerikanische Wirtschaftsgemeinschaft bilden, nämlich — von Norden nach Süden — Guatemala, El Salvador, Honduras, Nicaragua und Costa Rica. Diese Länder umfassen ein Gebiet von 440 718 km^2. Nachstehend die Größen der einzelnen Länder:

	Gebiet (km^2)
Guatemala	108 889
El Salvador	21 041
Honduras	112 088
Nicaragua	148 000
Costa Rica	50 700

Topographie

Die Topographie der zentralamerikanischen Region ist sehr unterschiedlich; man kann sie jedoch in zwei Haupt-Topographiegebiete unterteilen:

1. Das zentrale Hochland einschließlich nördliche und südliche Gebirgsregionen, die Vulkankette am Pazifik und die damit verbundenen vulkanischen Hügel und Hochebenen, und
2. das Tiefland mit dem Petén-Gebiet von Nord-Guatemala und die pazifischen und karibischen Küstenebenen.

- Hochland.
  Ein beachtlicher Teil von Guatemala, Honduras und Nordwest-Nicaragua wird von der nördlichen zentralamerikanischen Gebirgskette mit Erhebungen über 1000 - 4000 m über NN bedeckt. Die südliche Gebirgskette von Zentral-Costa Rica durchzieht dieses Land von Norden nach Süden und reicht bis in den westlichen Teil Panamas.
  Die Vulkankette verläuft entlang einer geologischen Verwerfung, die sich fast parallel zur Pazifikküste erstreckt. Diese Kette entsteht an der Grenze zwischen Mexiko und Guatemala (Tacana Vulkan) und erstreckt sich in südöstlicher Richtung durch Guatemala bis zum Chingo-Vulkan an der Grenze zu El Salvador. Sie durchzieht El Salvador in ost-westlicher Richtung und verläuft dann südöstlich nach Nicaragua bis in den Norden von Costa Rica.

+ Die Bevölkerungszahlen, Kosten und anderen sich zeitlich ändernden Daten in diesem Kapitel, sowie die Ausdrücke "gegenwärtig" oder "in diesem Jahr" beziehen sich auf das Jahr 1979.

5. ROOFING IN CENTRAL AMERICA +

5.1 General Considerations

5.1.1 Topography, Climate and Natural Hazards

Geographically, the Central American Isthmus extends from the Tehuantepec Isthmus in Mexico to the Atrato lowlands in Columbia; however, for the purposes of the present study, only the five nations which make up the Central American Common Market have been considered. These include, from north to south, Guatemala, El Salvador, Honduras, Nicaragua and Costa Rica. These countries represent a total land area of 440 718 square kilometers and the relative size of each is as follows:

	Area (km^2)
Guatemala	108 889
El Salvador	21 041
Honduras	112 088
Nicaragua	148 000
Costa Rica	50 700

Topography

The topography of the Central American region is quite variable, but can be considered to consist of two principal topographical divisions:

1. the Central highlands including the northern and southern mountain ranges, the Pacific chain of volcanoes and the volcanic hills and plateaus associated with the chain; and
2. the lowlands which include the Petén area of Northern Guatemala and the Pacific and Caribbean coastal plains.

- Highlands.
  A considerable portion of Guatemala, Honduras and northwest Nicaragua is covered by the northern Central American mountain range with elevations above sea level of 1000 to 4000 meters. A secondary range of lesser elevations extends from this system into El Salvador. The southern mountain range located in Central Costa Rica crosses this country from north to south and extends into the western portion of Panama.
  The chain of volcanoes follows a geological fault which runs approximately parallel to the Pacific coast. This chain originates on the border between Mexico and Guatemala (Tacana Volcano) and extends in a southeast direction through Guatemala to the Chingo Volcano located on the border with El Salvador. It crosses El Salvador in an east-west direction and then turns southeast in Nicaragua extending into northern Costa Rica.

+ The population figures, prices and other data given in this section which change with time, as well as the terms "present" or "in this year" refer to the year 1979.

Die früheren Vulkantätigkeiten in dieser Region bildeten viele vulkanische Hügel und Hochebenen sowie weite Täler mit vulkanischem Gestein. Einige wichtigere Bevölkerungszentren liegen in diesen Tälern, z.B. Quetzaltenango, Guatemala; Santa Ana, El Salvador und San José, Costa Rica.

- Tiefland.
  Tiefebenen erstrecken sich entlang der gesamten pazifischen und karibischen Küste von Zentralamerika und sind im allgemeinen nicht höher als 200 m mit entweder flacher oder leicht ansteigender Topographie. Diese Tiefebenen entstanden in einigen Gebieten durch angeschwemmte Ablagen und in anderen Gebieten durch Erosion älterer Felsbildungen.
  Das nördliche Petén-Gebiet von Guatemala ist ein weites, flaches, stark bewaldetes Tiefland, welches fast 50% des gesamten Landes ausmacht, mit jedoch nur einem Prozent seiner Einwohner. Die niedrige Bevölkerungszahl liegt zum großen Teil an dem landwirtschaftlich wenig ertragreichen Gebiet mit einer dünnen Schicht Mutterboden auf porösem Kalkuntergrund.

Vegetation

- Karibische Küstenebene.
  Die dünn besiedelte karibische Küstenebene ist das Gebiet, welches gegenwärtig die weitest ausgedehnten Wälder von Zentralamerika hat, besonders entlang der Küste von Nicaragua und im Petén-Gebiet von Guatemala, wo man die Vegetation im allgemeinen als tropischen Regenwald einordnen kann. Diese Wälder bestehen aus großen, breitblättrigen Laubbäumen mit kleineren Bäumen, Büschen und Schattengewächsen als Unterholz.
  Entlang der Karibikküste besteht die landwirtschaftliche Aktivität hauptsächlich im Anbau von Bananen in Costa Rica, Honduras und, in geringerem Umfang, in Guatemala. In Honduras findet man auch Plantagen mit afrikanischen Palmen, die zur Speiseölgewinnung kultiviert werden. Kokosnußpalmen wachsen überall in diesem Gebiet, werden jedoch kaum zu kommerziellen Zwecken kultiviert.

- Zentrales Hochland.
  Pinien, Zypressen und verschiedene Arten von Laubbäumen bilden die natürlichen Wälder des zentralamerikanischen Hochlands. Die größten Pinienwälder befinden sich zur Zeit in Honduras, wo Pinienholz ein wichtiger Exportartikel ist. Ausnahmen gibt es in kleinen Gebieten von Nicaragua und Honduras und in einem Gebiet von etwa 300 km^2 in Zentral-Guatemala, wo wegen der geringen Niederschläge eine wüstenähnliche Vegetation von Zwergbäumen, Kakteen und anderen Dürre-unempfindlichen Pflanzen entstanden ist.
  Es ist der großen Bevölkerungsdichte in den Hochland-Gebieten zuzuschreiben, daß ein großer Teil des natürlichen Waldes vernichtet und das Land für landwirtschaftliche Zwecke genutzt wurde. Es ist dasjenige Gebiet, wo man die meisten Kleinfarmen (milpas) findet, welche Korn, Bohnen und Gemüse pflanzen, was oft nur als Existenzminimum reicht.
  Kaffeeplantagen bilden den Hauptanteil der landwirtschaftlichen Produktion in den Hochlandgebieten. Diese Plantagen haben waldähnlichen Charakter, da Kaffee gewöhnlich im Schatten von Laubbäumen wächst. Andere für den Verkauf be-

The past volcanic activity in this region has resulted in the formation of many volcanic hills and plateaus as well as wide valleys filled with volcanic materials. Some of the more important population centers are located in these valleys, for example: Quetzaltenango, Guatemala; Santa Ana, El Salvador and San José, Costa Rica.

- Lowlands.
  Lowland plains extend along the entire Pacific and Caribbean coastlines of Central America and are generally of elevations less than 200 m with either flat or gently sloping topography. These lowlands were formed in some areas by alluvial deposits, and in others, by erosion of the older rock formations.
  The northern Petén area of Guatemala is an extensive flat heavily forested lowland region which accounts for almost 50 per cent of the nation's land area, but only one per cent of its inhabitants. The low population figure is due in great part to the poor agricultural potential of this area, which possesses a very thin layer of topsoil covering a porous limestone base.

Vegetation

- Caribbean coastal plain.
  The sparcely populated coastal plain is the region which presently contains the largest forest extensions in Central America, particularly along the Nicaraguan coast and in the Petén area of Guatemala where the vegetation can be generally classified as a tropical rain forest. These forests consist of tall broad-leafed deciduous trees with an undergrowth of smaller trees, bushes and shade-growing plants.
  The major agricultural activity along the Caribbean coast is the cultivation of bananas in Costa Rica, Honduras and, to a lesser extent, Guatemala. Plantations of African palm trees grown as a source of edible oil, also are found in Honduras. Coconut palms grow throughout the region, but rarely are cultivated for commercial purposes.

- Central highlands.
  Pine, cypress and various species of deciduous trees make up the natural forests of the Central American highlands. The largest pine forests today are located in Honduras, where pine lumber is an important export product. Exceptions are formed in small areas in Nicaragua and Honduras and in an area of about 300 square kilometers in Central Guatemala, where conditions of low rainfall have resulted in a desertlike vegetation of dwarf trees, cactus and other drought-resistant plants.
  Due to the high population density of the highland regions, much of the natural forest has disappeared and the land converted to agricultural use. This is the region where most mini-farms (milpas) are found, producing corn, beans and vegetables, often at a subsistence level.
  Coffee plantations represent the most important large scale agricultural activity in the highlands. These plantations exhibit some forestlike characteristics since coffee is grown in shade usually provided by deciduous trees. Other commercial highland crops include wheat, sorghum, peanuts, highland rice and a great va-

stimmte Hochland-Produkte sind Weizen, Sorghum, Erdnüsse, Hochland-Reis und eine Vielfalt von Früchten und Gemüse.

- Pazifische Küstenebene.
  Obwohl das Klima der pazifischen Küstenebene demjenigen der karibischen Küste ähnelt, hat diese Region eine viel größere Bevölkerungsdichte und Vielfalt, was die landwirtschaftlichen Möglichkeiten betrifft, aufgrund ihres fruchtbaren Bodens und der kürzeren Entfernung zu den wichtigsten Bevölkerungszentren des Hochlands. In diesem Gebiet gibt es noch einige Wälder, aber man kann sagen, daß es praktisch fast ausschließlich aus Ackerland besteht.
  Hauptsächlich wird das Land für Viehzucht und die Herstellung von Baumwolle, Zuckerrohr und Tiefland-Kaffee genützt. Die afrikanische Palme wird in großem Ausmaß an der Pazifikküste von Costa Rica gepflanzt; Gummiplantagen gibt es in Guatemala. Reis, Getreide, Früchte und Gemüse werden ebenfalls in der Küstenebene erzeugt.

riety of fruits and vegetables.

- Pacific coastal plain.
  Although the climate of the Pacific coastal plain is similar to that of the Caribbean coast, this region has a much greater population and variety of agricultural activities due to its more fertile soil and greater proximity to the major highland population centres. Few forests still exist in the region, and for practical purposes it can be considered to consist almost exclusively of farmland. The major land use is for cattle raising and the production of cotton, sugar cane and lowland coffee. The African palm is cultivated extensively on the Pacific coast of Costa Rica, and rubber plantations exist in Guatemala. Rice, grains, fruits and vegetables also are produced on the coastal plain.

Abb. 5.1 ZENTRALAMERIKA : Topographische Karte mit pazifischer Vulkankette

Fig. 5.1 CENTRAL AMERICA : Topographical map showing Pacific chain of volcanoes

Klima

Das Klima der gesamten zentralamerikanischen Region kann im allgemeinen als tropisch bezeichnet werden, mit ziemlich exakt zu bestimmenden Regen- und Trockenzeiten.

Örtlich wird das Klima in drei Kategorien aufgeteilt: heiß, gemäßigt oder kalt, hauptsächlich je nach Höhenlage. Das "heiße" Klima mit Durchschnittstemperaturen zwischen 23 und 32°C herrscht im Tiefland vor bis zu einer Höhe von ca. 800 - 900 m, es umfaßt beide Küstenebenen, Süd-Mittel-Nicaragua und das Petén-Gebiet von Guatemala. Das gemäßigte Klima (Durchschnittstemperatur 17 - 23°C) findet man gewöhnlich bei 900 - 1900 m Höhe, während das "kalte" Klima mit Temperaturen unter 17°C in darüberliegenden Höhenlagen anzutreffen ist. Die niedrigste Temperatur in Zentralamerika (5°C) wurde am Gipfel des Tajumulco-Vulkans in Guatemala gemessen.

Climate

The climate of the entire Central American region generally can be considered as tropical, with fairly clearly defined rainy and dry seasons.

Locally, climate is classified in three categories: hot, temperate or cold, depending principally upon land elevation. The "hot" climate with average temperatures between 23 and 32°C prevails in the lowlands up to elevations of about 800 - 900 m, including both coastal plains, south-central Nicaragua and the Petén area of Guatemala. The temperate climate (average temperature of 17 to 23°C) is usually found at elevations of 900 to 1900 m; while "cold" climates with temperatures below 17°C occur at still higher elevations. The lowest temperature in Central America (5°C) was measured at the summit of the Tajumulco Volcano in Guatemala.

Abb. 5.2 ZENTRALAMERIKA : Jahresniederschlagsmenge

Fig. 5.2 CENTRAL AMERICA : Annual precipitation

Ziemlich strenge Nordwinde sind in den Hochlandregionen von Guatemala, Honduras und Nord-Nicaragua normal aufgrund des Durchzugs polarer Luftmassen durch Nordamerika während der Wintermonate. Weil Mittelamerika auch eine schmale und sehr gebirgige Landenge ist, findet man in den Küstengebieten viele verschiedene Windbedingungen sowohl im Seebereich wie auf dem Land.

Obwohl es örtliche Unterschiede gibt, ist die Regenzeit für alle zentralamerikanischen Länder ziemlich die gleiche; sie beginnt im Mai und erstreckt sich bis in den Oktober. Regen fällt normalerweise als tropische Wolkenbrüche, die sehr oft von Gewittern begleitet sind. Hagelstürme ereignen sich in Hochlandgebieten, und Wirbelstürme streifen gelegentlich die nördliche karibische Küste in den Monaten September und Oktober.

Die jährliche Regenmenge ist in der Region sehr unterschiedlich. Die Gebiete mit der niedrigsten Regenmenge (weniger als 1000 mm) liegen in den Hochländern von Guatemala und Honduras. Der meiste Regen fällt an der Karibikküste von Nicaragua mit einer jährlichen Niederschlagsmenge von bis zu 6.000 mm.

Naturereignisse

Die in Zentralamerika vorherrschenden Naturereignisse umfassen Erdbeben und Vulkanausbrüche sowie Wirbelstürme, Hagelstürme und Überschwemmungen während der Regenzeit.

- Erdbeben.
  Erdbeben stellen die größte Gefahr für Leben und Besitz dar. In diesem Jahrzehnt erlebte Zentralamerika die folgenden beiden Katastrophen:

  1. Am 23. Dezember 1972 wurden 60% der Stadt Managua, Nicaragua, durch ein heftiges Erdbeben zerstört; es gab über 14.000 Tote und nahezu 200.000 Obdachlose.
  2. Am 4. Februar 1976 verwüstete eine Serie von Beben in Guatemala, mit einer Stärke von 7.6 auf der Richterskala, weite Gebiete der Republik und berührte 20 der 22 Departments. Mehr als 24.000 Menschen verloren ihr Leben, und über 1.200.000 wurden obdachlos.

Auf den Seiten 98 und 99 :

Abb. 5.3 Typischer Erdbebenschaden mit sichtbarem Ringbalken, der den Einsturz des Hauses verhinderte: Adobe-Mauerwerk, Holzringbalken, verzinktes Wellblechdach.

Abb. 5.4 Notbehausungen nach dem Erdbeben (vom Roten Kreuz bereitgestellt): Holzrahmen und -wandkonstruktion, verzinktes Wellblechdach.

Fairly strong northerly winds are common in the highland regions of Guatemala, Honduras and northern Nicaragua, as a result of the effect of the movement of polar air masses across North America during the winter months. Also, since Central America is a narrow and very mountainous isthmus, many variable sea and land breeze conditions are found in coastal areas.

Although local variations exist, the rainy season for all of the Central American nations is roughly the same, starting in May and extending through October. Rainfall usually is in the form of tropical cloudbursts often accompanied by thunder and lightning. Hailstorms occur in highland areas, and hurricanes occasionally strike the northern Caribbean coast in the months of September and October.

The amount of annual precipitation varies widely throughout the region. The areas of lowest rainfall (less than 1000 mm) are found in the Guatemalan and Honduran highlands. Heaviest rainfall occurs on the Caribbean coast of Nicaragua where the annual precipitation reaches a maximum of 6000 mm.

Natural hazards

The climatic and seismic hazards prevalent in Central America include earthquakes and volcanic eruptions as well as hurricanes, hailstorms and floods during the rainy season.

- Earthquakes.
  Earthquakes represent the greatest hazard to life and property. During the present decade, Central America has experienced the following two catastrophes:

  1. On December 23, 1972, 60% of the city of Managua, Nicaragua, were destroyed by a violent earthquake which resulted in over 14 000 deaths, and approximately 200 000 persons homeless.
  2. On February 4, 1976, a series of tremors in Guatemala, starting with one of Richter 7.6, devastated large areas of the Republic, affecting 20 of the 22 Departments. Over 24 000 persons were killed, and more than 1 200 000 left without homes.

Fig. 5.3 Typical earthquake damage, showing the ring beam which prevented collapse of the building: adobe walls, timber ring beam, corrugated galvanized iron roof.

Fig. 5.4 Post-earthquake emergency dwellings (supplied by the Red Cross): timber framework and walls, corrugated galvanized iron roof.

Zusätzlich zu den unheilvollen Erdbeben wird das Gebiet fast ständig von weniger starken Beben erschüttert. Guatemala berichtet über jährlich ca. 300 Beben, wovon ca. 1% gefährlich sein kann. Am 9. Oktober 1979 herrschte im Department of Santa Rosa ein Beben (Richter 5.8), welches über 200 Häuser zerstörte. Alle hatten Adobe- oder Bajareque-Wände, 75% Ziegeldächer und 25% Zinkblechdächer.
Seit dem letzten Erdbeben haben viele zentralamerikanische Regierungen die örtlichen Bauvorschriften verschärft, indem sie viele Anforderungen aus den strengen Bauvorschriften des Staates Californien, USA, übernahmen. Dies betrifft jedoch hauptsächlich den Bau von öffentlichen und kommerziellen Gebäuden in den größeren Städten. In den ländlichen Gebieten von Guatemala, wo es keine Bauvorschriften gibt, haben verschiedene Organisationen die örtliche Bevölkerung über sichere Bautechniken für Häuser mit Adobewänden unterrichtet, indem sie empfahlen, Zinkblechdächer oder Asbestzementdächer statt der gefährlicheren Ziegeldächer anzuwenden.

- Vulkanausbrüche.
  Außer in Honduras ereignen sich Vulkanausbrüche in allen zentralamerikanischen Ländern. Obwohl der unmittelbare Schaden nur ein kleines Gebiet betrifft, können Sand und Asche des Ausbruchs beträchtliche Flächen bedecken und somit die Ernte vernichten und aufgrund der Ablagerungen auf den Dächern Häuser beschädigen. In nur wenigen Fällen brach Feuer aus durch die heiße Vulkanasche, die auf Strohdächer fiel.

- Wirbelstürme.
  Tropische Stürme mit 35 - 65 Knoten Geschwindigkeit und Wirbelstürme (Windgeschwindigkeit über 65 Knoten) treffen gelegentlich die nördliche karibische Küstenlinie und in der Hauptsache die Küsten von Honduras. Der letzte Wirbelsturm war Fifi (14. September 1974), der etwa 5.000 Menschenleben kostete und 100.000 Personen obdachlos machte.

- Hagelstürme.
  Hagelstürme ereignen sich in ganz Zentralamerika, meistens zwischen Mitte April und Mitte Juni. Obwohl sie in erster Linie der Ernte schaden, können sie auch Dachziegel beschädigen. Strohdächer werden davon nicht betroffen.

- Überschwemmungen.
  Überschwemmungen während der Regenzeit ereignen sich meist in der pazifischen Küstenebene, es gibt aber auch Überflutungen in Hochlandgebieten durch übertretende Flüsse. Überschwemmungen stellen eine gewisse Gefahr für Häuser dar, jedoch nicht direkt für die Dächer.

In addition to the disastrous earthquakes, the region is almost constantly subjected to tremors of lesser magnitude. Guatemala annually reports about 300 tremors, about 1% of which can be hazardous. On October 9 of this year, a tremor (Richter 5.8) occurred in the Department of Santa Rosa, resulting in the destruction of over 200 homes. All had adobe or bajareque walls, 75% with clay tile roofs and 25% with galvanized steel.
Since the recent earthquakes, many Central American Governments have tightened local building codes, adopting many of the requirements stipulated in the stringent building code of the State of California, U.S. This, however, affects principally the construction of public and commercial buildings in the larger cities. In the rural areas of Guatemala, where building codes do not exist, various organizations have been instructing the local population in safer construction techniques for adobe-walled houses and recommending the use of galvanized steel or asbestos-cement roofing instead of the more dangerous clay tile.

- Volcanic eruptions.
  Volcanic eruptions occur in all of the Central American nations, except Honduras. Although the direct hazard only involves a very small area, sand and ash from the eruption can cover considerable extensions, causing damage to crops and occasionally representing a hazard to housing due to the accumulation of debris on the roof. Few cases are known of fires caused by hot volcanic ash falling on thatch roofs.

- Hurricanes.
  Tropical storms with winds of 35 to 65 knots and hurricanes (windspeed over 65 knots) occasionally strike the northern Caribbean coastline, principally affecting the coast of Honduras. The last hurricane to strike this region was Hurricane Fifi (September 14, 1974) which caused about 5000 deaths and left 100 000 persons homeless.

- Hailstorms.
  Hailstorms occur throughout Central America, usually between mid-April and mid-June. Although primarily a hazard to crops, hailstones can damage clay roof tiles. Thatch roofs are not affected.

- Floods.
  Flooding during the rainy season occurs most frequently on the Pacific coastal plain, but there also is some localized flooding in highland areas caused by swollen rivers. Floods obviously represent some hazard to housing, but do not directly affect roofs.

5.1.2 Bevölkerung, Kultur und Traditionen

Die Gesamtbevölkerung der fünf zentralamerikanischen Länder beträgt zur Zeit etwa 20 Millionen und wird im Jahre 2000 voraussichtlich 35 Millionen betragen. Die für 1980 geschätzte Bevölkerungszahl teilt sich auf die verschiedenen Länder wie folgt auf:

Land	Personen in Tausend	Prozent
Costa Rica	2.286	11,26
El Salvador	4.813	23,71
Guatemala	6.940	34,18
Honduras	3.595	17,71
Nicaragua	2.669	13,14
Insgesamt	20.303	100,00

5.1.2 Population, Culture and Traditions

The total population of the five Central American countries presently is about 20 million, and is expecred to reach 35 million inhabitants in the year 2000. The population per country estimated for 1980 is as follows:

Country	Thousands of Persons	Percent
Costa Rica	2 286	11.26
El Salvador	4 813	23.71
Guatemala	6 940	34.18
Honduras	3 595	17.71
Nicaragua	2 669	13.14
Total	20 303	100.00

Abb. 5.5 ZENTRALAMERIKA : Bevölkerungsdichte

Fig. 5.5 CENTRAL AMERICA : Population density

Da die gesamte Fläche dieser Region etwa 440.000 km^2 umfaßt, stellen die oben genannten Zahlen eine durchschnittliche Bevölkerungsdichte von 46 Bewohnern/km^2 dar. Die Bevölkerung ist jedoch nicht gleichmäßig über das Land verteilt, sondern hauptsächlich auf das zentrale Hochland und die Pazifikküste konzentriert. Weite Gebiete entlang der Atlantikküste und im nördlichsten Department von Guatemala (El Petén) sind sehr dünn besiedelt.

Ackerbau ist die wirtschaftliche Hauptaktivität in allen fünf zentralamerikanischen Ländern. Nur ca. 30% der regionalen Bewohner werden der städtischen Bevölkerung zugerechnet (1); die restlichen 70% leben in ländlichen Gebieten, die meisten davon sind hauptsächlich im Ackerbau beschäftigt. Dies sind Kleinbauern, die vorwiegend Getreide und Bohnen erzeugen, wandernde Landarbeiter, die zur Erntezeit auf großen Plantagen angestellt werden (Kaffee, Zuckerrohr, Baumwolle, Bananen), und ständige Angestellte der großen Plantagen. Der letzteren Gruppe wird vom Plantagenbesitzer die Wohnung gestellt, die aus leicht zu installierenden vorgefertigten Materialien für die Dachdeckung (Zinkblech oder Asbestzement) bestehen. Die Mehrzahl der übrigen ländlichen Bevölkerung baut ihre Häuser mit traditionellen Materialien.

Die ethnische Aufteilung der Bevölkerung ist in El Salvador, Honduras und Nicaragua ähnlich, mit "ladinos" (indianisch-europäische Mischung), die ungefähr 85% der zusammengesetzten Bevölkerung dieser drei Länder ausmachen. Die übrige Bevölkerung umfaßt Personen europäischen Ursprungs, Indianer, und einen kleinen Prozentsatz farbiger Einwanderer von den karibischen Inseln.

Guatemala unterscheidet sich von den anderen Ländern etwas dadurch, daß mehr als 50% der Bevölkerung sich aus Indianern mit Maya-Quiché-Ursprung zusammensetzen, die immer noch ihre eigenen Bräuche und ihre Sprache aufrechterhalten. Auf der anderen Seite hat Costa Rica einen unbedeutenden Anteil an indianischer Bevölkerung, und die große Mehrheit seiner Bewohner ist europäischen Ursprungs.

Die Verschmelzung indianischer und europäischer (spanischer) Kulturen brachte zwei Typen traditioneller Dachdeckung hervor, die heute in ländlichen Gebieten Zentralamerikas, außer Costa Rica, vorherrschen. Dieses sind Stroh- oder Palmblatt-Dächer auf Pfosten- oder Bambus-Unterbau, die man vor allem in indianischen Dörfern sieht, und das rote Tonziegeldach, das von spanischen Siedlern eingeführt wurde.

Von den beiden oben genannten Systemen wird das Tonziegeldach sozial höher eingestuft, obwohl herunterfallende Ziegel während des Erdbebens in Guatemala im Jahre 1976 viele Menschen töteten. Dieser Dach-Typ ist optisch attraktiv und relativ frei von Insekten, was bei Strohdächern problematisch ist. Seine relativ hohen Kosten halten jedoch viele ländliche und städtische Bewohner von seinem Gebrauch ab.

In Costa Rica, dem Land mit dem höchsten Pro-Kopf-Einkommen in Zentralamerika, haben vorgefertigte Dachdeckungsmaterialien die traditionellen Systeme weitgehend verdrängt. Man findet jedoch immer noch einige Ziegel- und Strohdächer in diesem Land.

(1) Bewohner von Städten mit 10.000 oder mehr Einwohnern

Since the total land area of this region is approximately 440 000 square kilometers, the above figure represents an average population density of 46 inhabitants/square kilometer. However, in fact the population is not distributed evenly throughout the region, but is concentrated principally in the Central highlands and on the Pacific coast. Large areas along the Atlantic coast and in the northernmost department of Guatemala (El Petén) are very sparsely populated.

Agriculture is the primary economic activity in all five of the Central American nations. Only about 30 percent of the regional inhabitants are classified as urban dwellers (1); the remaining 70% live in rural zones with the vast majority engaged in agricultural activities. These include permanent small farmers producing principally corn and beans, itinerant farm workers who are employed by large plantations at harvest time (coffee, sugar cane, cotton, bananas), and the permanent employees of the large plantations. This latter group frequently is provided with housing by the plantation owner, usually using easily installed manufactured materials for roofing (galvanized steel or asbestos cement). The majority of the rest of the rural population build their own homes using traditional materials.

The ethnic distribution of the population is similar in El Salvador, Honduras and Nicaragua, with "ladinos" (mixture of Indian and European) representing about 85% of the combined population of the three countries. The remainder includes persons of European extraction, Indians and a small percentage of black immigrants from the Caribbean Islands.

Guatemala differs from the other countries in that slightly more than 50% of the population is made up of Indians of Maya-Quiché descent who still maintain their own customs and language. Costa Rica, on the other hand, has an insignificant Indian population, and the great majority of its inhabitants are of European extraction.

The merging of the Indian and European (Spanish) cultures has resulted in two types of traditional roofing systems which today predominate in rural Central America, except for Costa Rica. These include the straw or palm leaf thatch roof, supported by a pole or bamboo substructure, which is very common in Indian villages, and the red clay tile roof which was introduced by the Spanish settlers.

Of the above two traditional systems, the clay tile roof has the higher degree of social acceptability, despite the fact that falling tiles were considered to be responsible for some deaths during Guatemala's 1976 earthquake. This type of roof is visually attractive and relatively free of the insect problem associated with thatched roofs. Its higher relative cost, however, prevents its use by many of the rural and urban poor.

In Costa Rica, the Central American nation with the highest per capita income, manufactured roofing materials have largely substituted the traditional systems. However, some clay tile and thatched roofs are still found in this country.

(1) Residents of cities with population of 10 000 or more.

5.1.3 Baumaterialien

Die in Zentralamerika verfügbaren Materialien, die gegenwärtig zum Hausbau verwendet werden, umfassen natürliche Materialien wie Ton, Stroh und Bambus, die von den Armen auf Feldern gesammelt werden; Tondachziegel und gebrannter Kalk, der von einfacher ländlicher Industrie hergestellt wird, Sägewerk-Holz und eine Anzahl moderner Baumaterialien, die von größeren Betrieben hergestellt werden, welche normalerweise in den größeren Städten angesiedelt sind.

Natürliche Materialien

Obwohl sie augenblicklich nicht direkt als Dachdeckungsmaterial verwendet wird, ist Erde wahrscheinlich das wichtigste natürliche Material aufgrund seiner Bedeutung für die Herstellung von Adobeblöcken, einem der wichtigsten in Zentralamerika angewandten Wandkonstruktionsmaterialien. Erde wird auch in Verbindung mit Holzpfählen, Rohr oder Bambus zur typischen "bajareque"-Wandkonstruktion verwendet, die man vor allem in indianischen Dörfern vorfindet.

Die natürlichen Materialien, welche für Strohdächer verwendet werden, sind verschieden, je nach Vorkommen natürlicher Vegetation in verschiedenen geographischen Zonen. Palmblätter werden meist sowohl in atlantischen als auch in pazifischen Küstenregionen verwendet. Im zentralen Hochland ist Stroh von verschiedenen grasähnlichen Pflanzen (1), die in diesen Gebieten reichlich vorhanden sind, das wichtigste Material. Bambus oder Pfähle aus Ästen oder kleinen Bäumen dienen als Unterkonstruktion für die Strohdächer.

Dächer dieses Typs werden hauptsächlich gebaut von Landbewohnern, die aus wirtschaftlichen Gründen keine vorgefertigten Materialien kaufen können, und machen einen bedeutenden Prozentsatz der gesamten Dachkonstruktionen in Zentralamerika aus, ausgenommen Costa Rica. Das Strohdach hat den Vorteil der niedrigen Kosten aufgrund der Verwendung von örtlichen Materialien, es hält das Hausinnere kühl und hält dem Aufprall von harten Gegenständen stand.
Seine Hauptnachteile liegen darin, daß sich Insekten oder Nagetiere einnisten, der Unterhaltungsaufwand groß und das Material nicht feuerbeständig ist.

Von kleinen ländlichen Betrieben hergestellte Materialien

Rote Tondachziegel werden in kleinen primitiven Brennöfen überall in Zentralamerika hergestellt. Nach einer kürzlichen ICAITI-Untersuchung arbeiten im Augenblick über 3.800 dieser Unternehmen in dem Gebiet. Kalk wird auch in ähnlichen ländlichen Einrichtungen hergestellt und hauptsächlich als Kalk-Sand-Mörtel für den Innenputz verwendet.

Die Tonziegel sind, wie vorher erwähnt, das beliebteste Dachdeckungsmaterial in vier der fünf zentralamerikanischen Länder, besonders im zentralen Hochland. Wegen der starken Vermehrung der kleinen Fabrikationsbetriebe und des fast vollständigen Fehlens von Produktionskontrollen, können Qualität und Abmessungen der ört-

(1) z.B. pajón (Epicampes macroura)

5.1.3 Building Materials

The materials available in Central America, which are currently used for housing construction, include natural materials such as clay, straw and bamboo which are gathered by the rural poor in the field, clay roof tiles and quicklime produced by primitive rural industries, sawmill lumber and a number of modern construction materials manufactured by larger industries usually located in the principal cities.

Natural materials

Although not presently used directly for roofing applications, earth or clay probably is the most important natural material because of its role in the fabrication of adobe blocks, one of the principal wall construction materials in use in Central America. Earth also is used in conjunction with wooden poles, canes or bamboo in the typical "bajareque" wall construction usually found in Indian villages.

The natural materials used for thatched roofs vary depending upon the type of vegetation available in different geographical zones. Palm leaves are used most frequently in both Atlantic and Pacific coastal regions. In the central highlands, straw obtained from various grasslike plants (1) which abound in these regions is the principal material. Bamboo or poles cut from branches or small trees serve as support members for the thatched roof.

Roofs of this type are constructed principally by rural inhabitants unable for economic reasons to purchase manufactured materials, and represent a significant percentage of total roof construction throughout Central America, except Costa Rica. The thatch roof has the advantage of low cost through the use of locally available materials, tends to maintain the house interior cool and resists the impact of solid objects. Its chief disadvantages lie in its tendency to become infested with insects or rodents, its relatively high maintenance requirements and lack of fire resistance.

Materials Produced by Small Rural Industries

Red clay roofing tiles are produced in small primitive kilns throughout Central America. According to a recent ICAITI survey, over 3 800 of these enterprises currently operate in the region. Lime also is produced in similar types of rural installations and is used primarily in lime-sand mortar for interior finishing.

The clay tiles, as mentioned previously, represent the most popular roofing material in four of the five Central American countries, especially in the central highlands. Due to the wide proliferation of the small manufacturing enterprises and the almost complete lack of production controls, the quality and dimensions of local roof tiles can vary considerably. The most common tile is the curved variety known locally as

(1) i.e. pajón (Epicampes macroura)

lichen Dachziegel beträchtlich variieren. Der gebräuchlichste Dachziegel ist die gebogene Ausführung, örtlich als spanischer oder arabischer Ziegel bekannt (Mönch- und Nonnen-Ziegel), der 40 cm lang, an einem Ende 18 cm und am anderen 14 cm breit ist und durchschnittlich 2,07 kg wiegt. Da man etwa 30 Ziegel benötigt, um 1 m^2 Dachfläche zu bedecken, beträgt alleine das Materialgewicht für diesen Dach-Typ ca. 62,05 kg/m^2.

Gegenwärtig werden diese Dachziegel für $ 0.15 verkauft. Der qm-Preis für die Dachdeckung beläuft sich somit auf ca. $ 4.50.

Das Ziegeldach ist leicht anzubringen und zu reparieren, hat eine relativ lange Lebensdauer und sorgt für eine gleichmäßigere Innentemperatur des Hauses. Es ist optisch attraktiv und erfreut sich bei den Bewohnern großer Beliebtheit.

Die Nachteile dieses Dachtyps liegen in seinem übermäßigen Gewicht, das eine schwerere Unterkonstruktion erfordert, und in der Tendenz, aufgrund von Verschiebungen einzelner Ziegel Lecks zu bilden. Auch sind die Ziegel leicht zerbrechlich, und bei Erdbeben können herunterfallende Ziegel den Bewohnern gefährlich werden.

Industriell gefertigte Materialien

Die wichtigeren Materialien, die in Zentralamerika industriell hergestellt werden, sind Portland-Zement, Löschkalk, Zementblöcke, gebrannte Tonziegel, Holz (Pinien und Harthölzer), verzinkte Stahl- und Asbestzementplatten.

Sperrholz und Preßspanplatten werden in dieser Region ebenfalls hergestellt, werden in der Bauindustrie jedoch hauptsächlich für leichte Trennwände und abgehängte Decken verwendet. Wellplatten aus fiberglasverstärktem Plastik sind ebenfalls verfügbar, aber wegen ihrer relativ hohen Kosten und kurzen Lebensdauer in erster Linie aufgrund ihrer Lichtdurchlässigkeit zur Überdeckung von Patios verwendet, wo Zierpflanzen gezogen werden.

- Portland-Zement.
  Portland-Zement für Beton wird in allen zentralamerikanischen Ländern hergestellt. Moderne Betonherstellung ist in dem Gebiet wohlbekannt. Sand und Kies sind reichlich verfügbar, und jedes Land hat wenigstens ein Walzwerk zur Herstellung von Bewehrungseisen. Gegossene Betondächer werden für die meisten öffentlichen und Verwaltungsbauten verwendet, ebenso für höher standardisierte private Wohnhäuser.
  Der gegenwärtige offizielle Preis (ab Werk) pro Zementsack (42,5 kg) liegt zwischen $ 2.10 und $ 2.29 überall in Zentralamerika. Eine kürzliche Knappheit in Guatemala hat jedoch die Preise auf durchschnittlich ca. $ 4.00 hochgetrieben. Zusätzliche Transportkosten können in ländlichen Gebieten einen Preis von mehr als $ 5.00 pro Sack Zement zur Folge haben.
  Das gegossene Betondach ist das teuerste in Zentralamerika angewendete Dachdeckungssystem. Die geschätzten Kosten pro m^2 betragen zur Zeit $ 27.00. Darüber hinaus tragen die erforderlichen Stützpfeiler dazu bei, daß die Gesamtbaukosten steigen. Die Vorteile dieser Dachdeckungsart sind deren extrem lange Lebensdauer, ihre Resistenz gegen Beschädigung durch harte Gegenstände, Wasserundurchlässigkeit, Feuerfestigkeit und gute Wärmeisolierung.
  Viele der örtlichen Zementfabriken stellen auch Löschkalk her für Wandputz.

Spanish or Arabian tile, which has a length of 40 cm, maximum and minimum widths, respectively, of 18 and 14 cm, and an average weight of 2.07 kg. Since about 30 tiles are required to cover one square meter of roof surface, the material weight alone for this type of roof is about 62.05 kg per square meter.

Presently these tiles are sold at a price of $ 0.15 per unit. The material cost for one square meter of roofing, therefore would be about $ 4.50.

The tile roof can be easily installed and repaired, has a relatively long life and maintains a more constant interior temperature in the home. It is visually attractive and enjoys a high level of popularity among the regional inhabitants.

The disadvantages of this type of roof system are its excessive weight which requires a heavier support structure and its tendency to develop leaks due to shifting of individual tiles. Also, the tiles can be easily broken and, during earthquakes, falling tiles can represent a hazard to the residents.

Manufactured Materials

The construction materials of more importance which are industrially manufactured in Central America include portland cement, hydrated lime, cement blocks, clay bricks, lumber (pine and hardwoods), galvanized steel and asbestos-cement sheets.

Plywood and composition board also are produced in the region, but in the construction industry are used principally for interior partitions and false ceilings. Corrugated roofing panels made of fiberglass reinforced plastic also are available, but due to their relatively high cost and short life, are used primarily to take advantage of their translucent properties in special applications, such as the covering of patios where ornamental plants are grown.

- Portland Cement.
  Portland cement for concrete is produced in all of the Central American countries. Modern concrete technology is well understood in the region; sand and gravel are readily available, and each country has at least one rolling mill for the manufacture of steel reinforcing rod. Poured concrete roofs are used for most public and commercial buildings, as well as for higher cost private residences.
  The present official price (fob factory), per bag of cement (42.5 kg), varies from $ 2.10 to $ 2.29 throughout the Central American region; however, a recent shortage in Guatemala has driven prices up to an average of about $ 4.00. Additional transportation costs can result in prices in rural zones in excess of $ 5.00 per bag of cement.
  The poured concrete roof is the most expensive roofing system in common usage in Central America. The cost per square meter currently is estimated to be $ 27.00. In addition, the need for support columns tends to raise overall building construction costs. The advantages of this type of roof are its extremely long life, resistance to the impact of solid objects, impermeability, fire resistance and good thermal insulation properties.
  Many of the local cement plants also produce hydrated lime for use in mortar for wall finishing.

- Zementblöcke und Tonziegel.
  In jedem Land gibt es einige Fabriken für die Herstellung von Zementblöcken und Tonziegeln, die Hauptmaterialien für Wandkonstruktionen bei höher standardisierten Gebäuden und bei öffentlichen Low-Cost-Housing-Projekten. Für private Unterkünfte in ländlichen Gebieten ist Adobe oder Bajareque immer noch das wichtigste Wandbaumaterial, mit Ausnahme von Costa Rica, wo Holzhäuser vorherrschen.

- Holz.
  Jedes Land hat eine Anzahl von Sägewerken zur Herstellung von Brettern und den geläufigeren Holzbauteilen. Pinienholz ist das gebräuchlichste Holz, aber andere Arten werden ebenfalls, hauptsächlich für dekorative Zwecke, verwendet. In Costa Rica ist Pinienholz das am häufigsten vorkommende Hausbaumaterial; in den anderen Ländern wird es für Dachtragkonstruktionen zusammen mit Tonziegeln, verzinktem Stahl oder Asbestzement-Dachdeckung, in höher standardisierten Gebäuden zum Innenausbau, und als Betonschalung verwendet. Die Anwendung von Holzschindeln zur Dachdeckung ist unbedeutend.
  Obwohl Rodungsprobleme Regierungsbeschlüsse zur Einschränkung von Holzverwendung in Zentralamerika zur Folge hatten, erscheint der gegenwärtige Vorrat von Pinienholz für die Erfordernisse der örtlichen Bauindustrie ausreichend zu sein. Der Preis ist jedoch relativ hoch mit durchschnittlich ca. $ 0.25 pro Brett-Fuß (ab Sägewerk).

- Verzinktes Stahlblech.
  Glattes und gewelltes verzinktes Stahlblech wird in mindestens einer Fabrik in jedem Land hergestellt. Da Zentralamerika keine Zinkvorkommen und keine Walzwerke zur Herstellung von Flachstahl hat, werden beide Hauptrohmaterialien (kaltgewalztes Stahlblech und Zinkbarren) importiert.
  Das fertige Produkt wird dem Verbraucher als Blech mit einer Größe von mindestens 6'(1,83 m) bis maximal 14'(4,27 m) angeboten. Die gebräuchlichste Breite ist ca. 30" (76 cm). Eine Stärke von 2,6 mm wird meist zur Dachdeckung verwendet, es gibt jedoch auch 2,8 und 3,0 mm-Bleche (1).
  Das durchschnittliche Gewicht des 2,6 mm-Materials beträgt ca. 4,1 kg/m^2. Der gegenwärtige Verkaufspreis ist $ 0.60 pro lfd Fuß (30" Breite), was einen qm-Preis von ca. $ 2.58 ausmacht. Es ist das preiswerteste Dachdeckungsmaterial, das in Zentralamerika verwendet wird.
  Die Vorteile des verzinkten Stahlblechs bei der Dachdeckung sind folgende:
  - geringes Gewicht, welches geringere Dimensionierung der Holztragkonstruktion zuläßt
  - relativ geringe Kosten
  - einfache Anbringung
  - Bleche können leicht entfernt und ersetzt werden
  - unempfindlich gegen Beschädigung mit harten Gegenständen
  - kann gestrichen werden, um die Optik und Korrosionsresistenz zu verbessern

(1) Obwohl das metrische System in allen zentralamerikanischen Ländern offiziell gilt, werden englische Einheiten im Geschäftsleben angewandt. In diesem Bericht werden die in Zentralamerika gebräuchlichen Maße angegeben und, wo erforderlich, die metrische Umrechnung in Klammern gesetzt.

- Cement Blocks and Clay Bricks.
  Various factories exist in each country for the manufacture of cement blocks and clay bricks which are the principal materials used for wall construction in higher cost buildings and in public low cost housing projects. For private dwellings in rural zones, adobe or bajareque still is the major wall construction material, except for Costa Rica where wooden homes are more common.

- Lumber.
  Each country has a number of sawmills which produce boards and the more common wooden structural members. Pine is the most common wood variety, but other species also are processed, principally for decorative uses. In Costa Rica, pine lumber is the major housing construction material; in the other countries it is used for roof support systems in conjunction with clay tile, galvanized steel or asbestos-cement roofing, interior applications in higher cost buildings and for forms for poured concrete. The use of wooden shingles for roofing is insignificant.
  Although deforestation problems have resulted in Government regulations to restrict timber operations in Central America, the present supply of pine lumber appears to be adequate for the needs of the local construction industry. The price, however, is relatively high, averaging about $ 0.25 per board foot (fob sawmill).

- Galvanized Steel Sheets.
  Smooth and corrugated galvanized steel sheets are produced in at least one factory in each country. Since Central America does not produce zinc and has no rolling mills suitable for flat steel, both of the principal raw materials (cold-rolled steel sheet and zinc ingots) are imported.
  The finished product is offered to the consumer in sheets with lengths varying from a minimum of 6' (1.83 m) to a maximum of 14' (4.27 m). The most common width is about 30" (76 cm). 26 gauge thickness is used most frequently for roofing applications, but 28 and 30 gauge sheets are also available (1).
  The average weight of the 26 gauge material is about 4.1 kg/square meter. The present retail price is $ 0.60 per linear foot (30" width), which represents a cost per square meter of approximately $ 2.58. This is the least expensive of the manufactured roofing materials in common usage in Central America.

  The advantages of galvanized steel for roofing applications are the following:
  - light weight which permits a reduction in size of the wooden support members
  - relatively low cost
  - simple installation
  - sheets can be easily removed and replaced
  - resists the impact of solid objects
  - can be painted to improve appearance and resistance to oxidation (red is the preferred color to simulate the appearance of the traditional red clay tile roof).

  The disadvantages are:
  - fairly rapid deterioration due to oxidation, especially in coastal areas

(1) Although the metric system is official in all of the Central American countries, English units are often used commercially. In this report, the dimensions commonly used in Central America are shown, with the metric equivalent, where required, in parantheses.

(Rot ist die bevorzugte Farbe, um die Erscheinung des traditionellen roten Tonziegeldaches zu imitieren).

Die Nachteile sind:
- ziemlich schnelle Verwitterung aufgrund von Oxydation, besonders in Küstengebieten
- Kondenswasserbildung im Inneren der Häuser, wenn nicht eine abgehängte Decke eingezogen wird (1)
- übermäßige Lärmbelästigung während Regenstürmen
- übermäßige Temperaturschwankungen im Inneren des Hauses

- Asbestzement.
Asbestzementplatten werden in Zentralamerika mittels örtlichem Portlandzement und importierter Asbestfaser hergestellt. Es werden vielerlei Formen hergestellt, einschließlich einfacher Wellplatten und trogförmiger Elemente mit besonders großen hochgezogenen Kanten (canaleta) bis zu einer Länge von 7 m.
Die einfache Wellplatte wird vom "do-it-yourself"-Bauherm bevorzugt. Dieses Material wird in 5 mm Stärke mit einem Gewicht von 10,5 kg/m^2 und in 6 mm Stärke mit einem Gewicht von 12,2 kg/m^2 hergestellt. Die Platten sind 1 m breit und sind zwischen 6'(1,83 m) und 10'(3,05 m) lang. Der Verkaufspreis für das natürliche graue Material (6 mm) liegt bei ungefähr ₡ 4.60/m^2. Rot-pigmentierte Platten (zur Imitation der roten Tonziegel) gibt es mit Aufpreis (₡ 5.27/m^2).
Die "canaleta", die mehr für öffentliche Billigwohnbauten verwendet wird, hat ein durchschnittliches Gewicht von 18,65 kg/m^2 und kostet durchschnittlich ₡ 6.46/m^2.
Asbestzement wird, hauptsächlich wegen seiner höheren Kosten und seines größeren Gewichts, weniger oft gebraucht als Zinkblech. Er ist jedoch das bevorzugte Dachdeckungsmaterial zum Bau von öffentlichen Billigwohnbauten durch staatliche Institutionen, und seine Verwendung auf diesem Gebiet gewinnt immer mehr an Bedeutung.
Die Hauptvorteile des Asbestzementdaches sind folgende:
- wasserdicht, feuerfest, rostbeständig
- ausreichende Steifigkeit, um auf Zwischenstützen verzichten zu können
- insektenresistent
- lange Lebensdauer

Die Nachteile sind:
- höherer Preis und größeres Gewicht als Zinkblech
- relativ zerbrechlich, z.B. beim Transport und beim Einbau, nicht unempfindlich gegen Beschädigung mit harten Gegenständen
- Anbringung komplizierter als bei Zinkblech
- Kondenswasserbildung im Inneren, falls nicht eine abgehängte Decke eingezogen wird
- Übermäßige Temperaturschwankungen im Inneren des Hauses

(1) Dies kann in ländlichen Gebieten zu einem ernsten Problem werden, wo der Hausbesitzer oft Getreide im Haus lagert.

- interior condensation problems unless a false ceiling is installed (1)
- excessive noise during rain storms
- excessive temperature changes inside of the home

- Asbestos-cement.
Asbestos-cement sheets are produced in Central America using locally manufactured Portland cement and imported asbestos fibre. Various section configurations are manufactured, including simple corrugated sheets and trough-shaped elements with special tall upturned ends (canaleta) up to 7 m long.
The simple corrugated sheet is preferred by the "do-it-yourself" builder. This material is offered in 5 mm thickness with a weight of 10.5 kg/m^2 and in 6 mm, with a weight of 12.2 kg/m^2. The sheets are 1 m wide with lengths varying from 6' (1.83 m) to 10' (3.05 m). The retail price for the natural gray-colored material (6 mm) averages about ₡ 4.60/m^2. A red pigmented sheet (to simulate clay tile appearance) also is available at a premium price (₡ 5.27/m^2).
The canaleta, used more frequently for public low cost housing, has an average weight of 18.65 kg/m^2 and an average cost of ₡ 6.46/m^2.
Asbestos-cement is used much less frequently than galvanized steel due principally to its higher cost and greater weight. However, it is the preferred roofing material for the construction of public low cost housing by institutions, and its use in this field is of increasing importance.

The main advantages of the asbestos-cement roof are as follows:
- waterproof, fireproof and rustproof
- sufficient rigidity to eliminate the need for intermediate supports
- resistant to attacks by insects
- long life

The disadvantages are:
- higher price and greater weight than galvanized steel
- relatively fragile, can be broken during handling and installation, lacks resistance to the impact of solid objects
- installation more complicated than galvanized steel
- interior condensation problems unless a false ceiling is installed
- excessive temperature changes in the home

(1) This can be a serious problem in rural zones where the home owner often stores grain inside of the house.

5.2 Gebräuchliche Bedachungssysteme

5.2.1 Quantitativer Vergleich bestehender Bedachungssysteme

Die auf den folgenden Seiten in Tabellen dargestellten Zahlen beziehen sich auf die wichtigsten Materialien, die für die Konstruktion von Wänden und Dächern in Zentralamerika verwendet werden. Für jedes der fünf Länder wird gemäß der letztgültigen Bestandsaufnahme aufgezeigt, wieviele Häuser jeweils aus den verschiedenen Materialien bestehen (1). Obwohl diese Daten 5 - 8 Jahre alt sind, sind sie ziemlich repräsentativ für die gegenwärtige Situation in allen Ländern, mit Ausnahme vielleicht von Guatemala, wo einige der Tondachziegel während des Erdbebens 1976 zerstört und durch Zinkblech ersetzt wurden.

Die relative (prozentuale) Häufigkeit jedes einzelnen Konstruktionssystems wird in den Diagrammen nach den Tabellen gezeigt. Für Zentralamerika insgesamt zeigt die vorliegende Information, daß Tonziegel, Stroh und Zinkblech bei 92% der Häuser verwendet werden, die restlichen 8% bestehen aus Asbestzement, Beton und anderen Materialien.

Strohdächer sind in Guatemala am stärksten vertreten (ca. 30%); sie sind von einiger Bedeutung in El Salvador, Honduras und Nicaragua, man findet sie jedoch nur selten in Costa Rica.

Die Tonziegel-Dachdeckung ist in allen Ländern sehr beliebt, mit Ausnahme von Costa Rica, wo sie nur bei weniger als 6% aller Häuser angewandt wird. Den höchsten Prozentsatz (68,59%) findet man in El Salvador.

Zinkblech ist am beliebtesten in Costa Rica, wo es bei 88% aller Wohnhausdächer verwendet wird. Die geringste Bedeutung hat es in El Salvador mit 7,42%.

Was Wandkonstruktionen betrifft, so sind in El Salvador, Guatemala und Honduras die traditionellen Adobe- und Bajareque-Systeme vorherrschend, während Holzkonstruktionen von größerer Bedeutung sind in Costa Rica (77,53%) und Nicaragua (45,65%).

5.2 Roofing Systems in Common Usage

5.2.1 Relative Importance of Existing Roofing Systems

The figures shown in the tables presented in the following pages refer to the principal materials used in the construction of roofs and walls for housing in Central America. The number of homes using each type of material, according to the latest census data available, is shown for each of the five countries (1). Although these data are five to eight years old, they are probably fairly representative of the present situation in all of the countries, except possibly Guatemala, where some of the clay tile roofs destroyed in the 1976 earthquake were replaced with galvanized steel.

The relative percentage importance of each construction system is shown in the diagrams following the tables. For Central America as a whole, the information presented shows that clay tile, thatch and galvanized steel are used on 92 percent of the homes, with asbestos-cement, concrete and other materials accounting for the remaining 8%.

Thatched roofs are most common in Guatemala (about 30% of the total), are of some importance in El Salvador, Honduras and Nicaragua, but are rarely found in Costa Rica.

The clay tile roofing system shows considerable popularity in all countries, except Costa Rica where it is used on less than 6 percent of total homes. The highest percentage (68.59%) occurs in El Salvador.

Galvanized steel is most popular in Costa Rica where it is used on 88% of all home roofs. It is of least importance in El Salvador (7.42%).

As far as wall construction is concerned, the traditional adobe and bajareque systems predominate in El Salvador, Guatemala and Honduras, while wooden construction is of greater importance in Costa Rica (77.53%) and Nicaragua (45.65%).

5.2.2 Typische Beispiele für bestehende traditionelle und handelsübliche Dächer

Baumethoden

- Strohdächer.
  Obwohl einige Strohdächer auf Adobe-, Stein- oder Ziegelhäusern anzutreffen sind, wird die Mehrzahl in Verbindung mit dem "bajareque"-Wandbausystem angewandt, eine Bauweise, die bis in die Maya-Kulturen zurückreicht, welche in Zentralamerika lange vor der Ankunft der spanischen Konquistadoren ihre Blütezeit hatte. Bei dieser Bauweise werden Baumgabeln oder Äste als Dachstützen verwendet, mit einer Fachwerkkonstruktion aus zusammengebundenen Pfählen oder Rohr, die zwischen den Stützen befestigt ist. Diese Rahmenkonstruktion wird allgemein mit kompaktierter Erde ausgefacht und manchmal mit Kalkschlämme bestrichen.
  Stroh wird für Dachdeckung in Hochlandgebieten, und Palmblätter in den Küstenebenen verwendet. Das Stroh wird in ca. 20 cm dicke Bündel gebunden und über einem 60° geneigten Rundholzrahmen befestigt. Die Befestigung sowohl der Rundhölzer als auch der Strohbündel erfolgt mittels einer natürlichen Weinrebe (mecate), die zuvor in Wasser eingeweicht wird, um durch die Schrumpfung beim Trocknen ein Festziehen der Knoten zu erreichen.
  Die 60° Dachneigung bildet einen großen Freiraum unter dem Dach innerhalb des Hauses, was zur Kühlung der Raumtemperatur beiträgt. Durch die starke Neigung kann Wasser schneller abfließen; dadurch wird die Möglichkeit der Leckbildung vermindert.
  Häuser dieses Typs werden sehr oft in Dörfern gebaut, und zwar vom Hausbesitzer selbst, was oft mit Hilfe von Freunden und Nachbarn geschieht. Das Binden des Strohs erfordert einiges handwerkliches Geschick, und nicht alle Dorfbewohner sind in der Lage, diese Arbeit auszuführen. Deshalb muß wenigstens eine Person mit dieser Fähigkeit im Bau-Team integriert sein.

- Tonziegel.
  Tonziegeldächer werden sehr häufig bei Häusern aus Adobe-Blöcken verwendet, in geringerem Ausmaß bei Zementblock-, Ziegel-, Holz- oder "bajareque"-Häusern. Häuser dieses Typs findet man vorwiegend in den meisten kleinen Städten in zentralamerikanischen Hochlandebenen (ausgenommen Costa Rica) und bei größeren Farmen. Sie können vom Hausbesitzer selbst oder auch von einem Bauunternehmer gebaut werden.
  Der Tonziegel wird normalerweise über einer Rahmenstützkonstruktion angebracht, obwohl gelegentlich eine flache Holzschalung aus 1" Pinienbrettern als Unterlage für die Ziegel verwendet wird.
  Bei der typischeren Dachkonstruktionsmethode dient ein Pinienholzrahmen aus 3" x 4"-Trauf- und Firstbalken und 2" x 3" (5,08 x 7,62 cm)-Sparren als Unterbau für die Ziegel. Der Freiraum zwischen den Sparren ist ebenso groß wie das schmalere Ende des Tonziegels.
  Der Rahmen wird zuerst mit einer Lage Ziegel mit nach oben gerichteten Seitenaufkantungen gedeckt; danach wird eine zweite Lage andersherum aufgelegt, wobei die Fugen der ersten Lage überdeckt und die unteren Ziegel mindestens

5.2.2 Typical Examples of Existing Traditional and Proprietary Roofs

Construction Methods

- Thatched Roofs.
  Although some thatched roofs are found on homes constructed with adobe, stone or brick walls, the majority are used in conjunction with the "bajareque" system of wall construction, a method dating back to the Mayan civilization which flourished in Central America long before the arrival of the Spanish "conquistadores". In this type of construction forked tree trunks or branches are used as roof support columns, with a wall framework formed of poles or canes tied together and installed in the spaces between columns. This framework is usually filled with compacted earth and is sometimes painted with a lime slurry.
  Straw is used for thatching in highland regions, and palm leaves on the coastal plains. The thatch is formed into bundles about 20 cm wide, and is tied in place over a pole framework installed with a pitch of 60°. Tying of both the pole frame members and the thatch bundles is accomplished using a natural vine (mecate) which is soaked in water beforehand to permit shrinkage to tighten the knots.
  The 60° pitch results in a large open space under the roof in the interior of the house which aids in maintaining a cooler inside temperature. The extreme slope also sheds water more rapidly minimizing the possibility of leaks.
  Homes of this type are constructed most frequently in rural villages and usually are built by the homeowner himself, often with the aid of friends and neighbors. The tying of the thatch requires some specialized manual skill, and not all village inhabitants are capable of performing this task; therefore, at least one person skilled in this art must be included in the construction team.

- Clay Tile.
  Clay tile roofs are used most frequently on homes with an adobe block wall construction, and to a much lesser extent with cement block, brick, wood or "bajareque". Homes of this type predominate in most small towns in the Central American highlands (except Costa Rica) and on the larger farms. They may be built by the homeowner or by a professional building contractor.
  The clay tile usually is installed over a frame support structure, although occasionally a flat wooden surface of 1" pine planks is used as a base for the tile.
  In the more typical roof construction method, a pine lumber frame is built consisting of 3" by 4" beams which form the edges and ridge, and 2" x 3" (5.08 x 7.62 cm) members running from the ridge to the lower edge of the roof, which support the tile. The free space between these supports is equal to the minor width of the truncated clay tile.
  The frame is first covered with a layer of tiles with curved ends up; a second layer is then set in place with curved ends down, covering the joints of the first layer and overlapping the bottom tiles by at least 7.5 cm. Only the first course

Abb. 5.12 Typisches traditionelles Strohdach aus Palmenblättern.
Fig. 5.12 Typical traditional thatched roof of palm leaves.

7,5 cm überlappt werden. Nur die erste Ziegelreihe am unteren Ende des Daches wird mit Kalkmörtel befestigt, um ein Herabgleiten zu verhindern; alle anderen Ziegel werden ohne Mörtel verlegt.
Durch diese Art der Dacheindeckung entstehen Zwischenräume zwischen den Ziegeln; dadurch wird genügend Luftzirkulation ermöglicht, um Kondenswasserprobleme zu vermindern und ein kühleres Innenraumklima zu schaffen.

- Verzinkter Stahl.
  Wie im vorhergehenden Abschnitt erwähnt, ist verzinkter Stahl gegenwärtig das wichtigste Dachdeckungsmaterial in Costa Rica, und es scheint auch in anderen zentralamerikanischen Ländern an Beliebtheit zu gewinnen. In diesen letzteren Ländern wurde es lange Zeit für Dächer auf temporären oder ständigen Hütten in

of tiles at the lower edge of the roof is fixed in place with lime mortar to prevent slippage; all other tiles are laid without mortar.
This type of installation leaves open spaces between the tiles which allow the circulation of air, producing enough ventilation to minimize condensation problems and to maintain a cooler interior temperature in the home.

- Galvanized Steel.
  As indicated in the previous section, galvanized steel currently is the principal roofing material used in Costa Rica, and appears to be gaining popularity in the other Central American nations. In these latter countries, it has long been used for roofs on temporary or permanent shacks built in urban slums and squatter settlements, but now is found also in rural areas where it is starting to substitute the

Abb. 5.13 Traditionelles Tonziegeldach (Mönch- und Nonnendeckung).
Fig. 5.13 Traditional clay tile roofing (Spanish type).

städtischen Slums und Squattersiedlungen verwendet, aber nun findet man es auch in ländlichen Gegenden wo es beginnt, die traditionellen Tonziegel- und Strohdächer zu verdrängen. Diese Tendenz ist am offensichtlichsten in Guatemala, wo die Angst vor Erdbeben die Beliebtheit des Tonziegeldaches zu dämpfen scheint. Verzinkte Stahlplatten sind leicht zu montieren und werden meist von "do-it-yourself"-Hausbauern verwendet. Dieses Material wird normalerweise über einem 2" x 4" (5,08 x 10,16 cm) Pinienholzrahmen mit einer Neigung von 20 - 25% befestigt.
Die verzinkten Wellblechplatten werden mit einer Längsüberlappung von 20 cm und einer seitlichen Überlappung entsprechend 1 1/2 Wellungen verlegt. Sie werden an den Ecken auf die Unterbauten genagelt und bei jeder dritten Welle in 30 cm Längsabständen mit großköpfigen verzinkten Nägeln.

traditional clay tile and thatch roofs. This tendency is most evident in Guatemala where fear of earthquakes may be dimming the popularity of the clay tile roof. Galvanized steel sheets are easily installed and are used most frequently by the "do-it-yourself" home builder. This material is normally installed over a 2" x 4" (5.08 x 10.16 cm) pine lumber frame with a pitch of 20 to 25%.
The corrugated galvanized sheets are laid with a longitudinal overlap of 20 cm and a lateral overlap equivalent to 1 1/2 corrugations. They are nailed to the supports at the edges and every third corrugation at 30 cm langitudinal intervals, using galvanized nails with large heads.

Abb. 5.14 Verzinktes Wellblechdach.
Fig. 5.14 Corrugated galvanized iron roof.

- Asbestzement.
  Wie bereits in vorangegangenen Abschnitten dieses Berichtes erwähnt, bieten die Asbestzementhersteller sowohl einfaches Wellasbest als auch Trogplattendeckung (canaleta) an, welche eine kompliziertere Profilierung hat. Die Wellplatten werden vom privaten Hausbauer bevorzugt, während die Trogplattendeckung, die weniger Holzstützen erfordert, das Hauptmaterial für Low-Cost-Housing-Projekte ist, die von öffentlichen Trägern durchgeführt werden.
  Die Wellasbestplatten werden über einem 2" x 4" (5,08 x 10,16 cm) Holzrahmen befestigt, der dem für die Dachdeckung mit verzinktem Blech ähnelt. Die seitliche Überlappung der Platten sollte ca. 1 Welle betragen, und die Längsüberlappung 15 cm. Der größte Abstand zwischen den Holzlatten ist 1,10 m für 5 mm dicke Asbestzementplatten, und 1,47 m für 6 mm dicke. Die Platten werden mit Nägeln oder Schrauben an den Latten befestigt, die Nagellöcher müssen vorher sorgfältig vorgebohrt werden.
  Die Trogplattendeckung kann Weiten bis zu 7 m ohne Zwischenauflager überspannen. Sie wird mit Nägeln oder Schrauben an den Mauerabschlußbalken befestigt; das Zusammenfügen der Platten erfolgt mittels Bolzen, Schraubenmuttern und Blei-, Zink- oder Asphalt-Unterlegscheiben.

- Stahlbeton.
  Stahlbetondächer werden bei höher standardisierten Privathäusern in ganz Zentralamerika angewendet, ebenso bei öffentlichen und Verwaltungsgebäuden. Dieser

Abb. 5.15 Asbestzement-Dach.
Fig. 5.15 Asbestos cement roof.

- Asbestos-cement.
  As mentioned in previous sections of this report, the asbestos-cement manufacturers offer both simple corrugated sheets and channel roofing (canaleta) which has a more complex section configuration. The corrugated sheets are preferred by the private home builder, while the channel roofing, which requires fewer wooden supports, is the principal material used by public institutions active in the low cost housing field.
  The corrugated asbestos-cement sheets are installed over a 2" x 4" (5.08 x 10.16 cm) wooden frame, similar to that used for galvanized steel. The lateral overlap between sheets should be about 1 corrugation, and the longitudinal overlap, 15cm. The maximum spacing between the wooden supports is 1.10 m for the 5 mm thick asbestos-cement sheets, and 1.47 for the 6 mm. The sheets are fastened to the supports with nails or screws, with all nailholes carefully perforated beforehand. The channel roofing can span distances up to 7 m without intermediate supports. It is fastened to the wall frame beams with nails or screws; the joining of sheets is accomplished with special bolts, nuts and lead, zinc or asphalt washers.

- Reinforced Concrete.
  Reinforced concrete roofs are used on higher priced private homes throughout Central America, as well as on public and commercial buildings. A professional building contractor usually constructs this type of roof.
  The construction procedure starts with the preparation of a pine lumber platform

Abb. 5.16 Stahlbeton-Dach.
Fig. 5.16 Reinforced concrete roof.

Dachtyp wird normalerweise von professionellen Bauunternehmern gebaut.
Die Gußform für das Betondach besteht aus einer Pinienholzschalung auf senkrechten Stützen. Ein Gitter aus Bewehrungsstahl, dessen Verbindungen mit Draht zusammengebunden werden, wird vorbereitet und in die Schalung gelegt. Das Gitter wird mit kleinen Steinen unterlegt, um einen Abstand von einigen Zentimetern zwischen dem Stahl und der Schalung zu erhalten.
Obwohl vorgemischter Beton in einigen der größeren Städte erhältlich ist, wird Beton normalerweise von Hand hergestellt (1 Teil Zement, 2 Teile Sand und 4 Teile Kies) und von Hand mit Eimern in die Form gegossen. Es stehen genügend Arbeitskräfte zur Verfügung, um das Dach in einem Tag fertigzustellen.
Das gegossene Betondach wird eine Woche lang täglich befeuchtet, und die Form wird normalerweise nach 15 Tagen entfernt. Zu diesem Zeitpunkt werden temporäre senkrechte Stützen angebracht und später, nach 28 Tage langer Erhärtung des Betons, wieder entfernt.

Kostenvergleiche

In der nachstehenden Tabelle werden vergleichbare Kosten für verzinkten Stahl, Asbestzement, Tonziegel- und Stahlbetondächer sowie Gesamtbaukosten unter Berücksichtigung verschiedener Wandbaumaterialien gezeigt. Diese Zahlen beinhalten Material und Lohn und wurden von öffentlichen Institutionen aufgestellt, die sich mit dem öffentlichen Wohnungsbau in Guatemala befassen (1).
Es existieren keine Kostenangaben über Strohdächer auf Bajareque-Wandkonstruktionen, da diese je nach Bauweise des Selbstbauers sehr unterschiedlich sind. Jedoch zeigen einige Kostenschätzungen, die auf diesem Gebiet in Guatemala durchgeführt wurden, daß die durchschnittlichen Gesamtbaukosten etwa $ 4,00/m² betragen können, wobei der Anteil für das Dach 50% ist.

Wohnungsbaukosten in Guatemala

Dachtyp	Wandkonstruktion	Gesamtbaukosten $/m²	Gesamtkosten Dach $/m²	% der Gesamtkosten
verzinktes Stahlblech	Zementblock	50.00	14.00	28
	Ziegel	70.00	14.00	20
	Adobe	40.00	14.00	35
Asbestzement	Zementblock	60.00	16.00	26
	Ziegel	90.00	16.00	18
	Adobe	45.00	16.00	36
Tonziegel	Zementblock	90.00	22.00	24
	Adobe	60.00	22.00	37
Stahlbeton	Zementblock	120.00	27.00	23
	Ziegel	160.00	27.00	17

(1) Banco Nacional de la Vivienda (BANVI). Banco Nacional de Desarrollo Agrícola (BANDESA).

with vertical supports which serves as the form for pouring the concrete roof. A grid of reinforcing rod with joints tied by wire is then prepared and placed over the platform. The grid is supported by small stones in order to leave a gap of several centimeters between the reinforcement and the platform surface.
Although pre-mixed concrete is available in some of the larger cities, concrete usually is mixed by hand (1 part cement, 2 parts sand and 4 of gravel) and manually poured into the form with buckets. Sufficient labor is provided to complete The poured concrete roof is moistened daily for one week, and the form is usually removed after 15 days. Temporary vertical supports are installed at this time and later removed after the concrete has been cured for 28 days.

Comparative Costs

In the following table, comparative costs are shown for galvanized steel, asbestos-cement, clay tile and reinforced concrete roofs, as well as total housing construction costs considering different wall materials. These figures include both material and labor costs, and were compiled by national institutions active in the public housing field in Guatemala (1).
Costs are not given for the thatched roof-bajareque wall construction, since these are extremely variable depending upon the procedures followed by the owner in the construction of his home. However, some estimates made in the field in Guatemala indicate that the average total construction cost may be about $ 4.00 /m² with the roof accounting for 50% of the total.

Housing Construction Costs in Guatemala

Roof Type	Wall Construction	Total Construction Cost $/m²	Total Cost Roof $/m²	% of Total Cost
Galvanized steel	Cement block	50.00	14.00	28
	Brick	70.00	14.00	20
	Adobe	40.00	14.00	35
Asbestos-cement	Cement block	60.00	16.00	26
	Brick	90.00	16.00	18
	Adobe	45.00	16.00	36
Clay tiles	Cement block	90.00	22.00	24
	Adobe	60.00	22.00	37
Reinforced concrete	Cement block	120.00	27.00	23
	Brick	160.00	27.00	17

5.2.3 Neue Entwicklungen

Die nachstehenden neuen Entwicklungen auf dem Gebiet der Dachkonstruktion in Zentralamerika wurden während örtlicher Untersuchungen durch ICAITI-Personal festgestellt.

- In Costa Rica wurde kürzlich ein neues industriell gefertigtes Dachdeckungsmaterial, bestehend aus asphalt-imprägniertem Karton in Form von Wellplatten, auf den örtlichen Markt gebracht.
- Ebenfalls in Costa Rica betreibt eine andere private Firma die Herstellung von Welldachplatten aus einer Mischung von Zement und gemahlenem Stein.
- In Guatemala macht das Engineering Department der National University Experimente mit Ferrozement-Dachelementen.
- Ebenfalls in Guatemala hat der dort ansässige Asbestzement-Hersteller ein neues Asbestzement-Dachpaneel entwickelt, das das Aussehen des Tondachziegels imitieren soll.
- In Honduras wurden Feldexperimente durchgeführt, um die ländliche Produktion von Zement-Faser-Wellplatten auszuwerten.

Asphalt-Karton-Paneele

Dieses in Costa Rica hergestellte Produkt wird örtlich unter dem Namen SUPERFLEX hergestellt. Es besteht offensichtlich aus Pappkarton oder ähnlichem mit Asphalt im-

5.2.3 New Developments

The following new developments in roofing in Central America were observed during the regional investigation by ICAITI personnel.

- In Costa Rica, a new manufactured roofing material, consisting of asphalt-impregnated cardboard formed into corrugated panels, has been recently introduced in the local market.
- Also in Costa Rica, another private industry is initiating the manufacture of corrugated roofing panels using a mixture of cement and crushed stone.
- In Guatemala, the Engineering Department of the National University is experimenting with ferrocement roofing elements.
- Also in Guatemala, the local asbestos-cement manufacturer has developed a new asbestos-cement roofing panel designed to simulate the appearance of clay tile.
- In Honduras, field experiments have been initiated to evaluate rural production of cement-fibre corrugated panels.

Asphalt-cardboard Panels

This product manufactured in Costa Rica is being sold locally under the brand name SUPERFLEX. It apparently consists of cardboard or similar material impregnated with

Abb. 5.17 Bitumen-Wellplatten mit schlechten Eigenschaften aufgrund von Materialschwäche (Costa Rica).

Fig. 5.17 Corrugated asphalt-based sheets, showing poor performance due to weak material (Costa Rica).

Abb. 5.18 Asbestzementplatten als Imitation von traditionellen Tonziegeln (Guatemala).

Fig. 5.18 Asbestos cement sheets simulating traditional clay tiles (Guatemala).

Abb. 5.19 Unkonventionelle Verwendung von Asbestzement-Trogplatten (canaletas), (Guatemala).

Fig. 5.19 Unconventional use of asbestos cement troughed sheets (canaletas), (Guatemala).

prägniertem Material und wird in drei Farben angeboten: Schwarz, Rot und Silber. Die Paneele sind gewellt und haben ähnliche Abmessungen wie die verzinkten Stahlbleche. Das Gewicht ist ungefähr 4 kg/m^2, und das Material kann genauso wie verzinkter Stahl installiert werden.
Der Preis ist niedriger als der des Konkurrenzproduktes (₡ 1,50/m^2), und das neue Material hat einige Beliebtheit gewonnen, besonders in Küstenregionen, wo das Rosten der verzinkten Stahldächer ein Problem ist. Da es jedoch Sonne und Regen ausgesetzt ist, weicht das Material auf, so daß die Wellen sich verflachen und verwinden. Außerdem ist das Material nicht feuerfest. Aufgrund dieser Nachteile wurde der Gebrauch des neuen Materials vom National Housing Institute eingestellt.

Zement-Stein-Dachdeckung

Eine weitere private Firma in Costa Rica entwickelt eine Wellplattendeckung, TECON, welche angeblich aus Zement und pulverisierten Steinen hergestellt ist, ohne irgendein weiteres Verstärkungsmaterial. Einige Vortests dieses Produkts durch das Material Laboratory des Costa Rica Housing Institute haben vielversprechende Ergebnisse gezeigt. Jedoch glauben Fachleute, daß das überhohe Materialgewicht, das 37 kg/m^2 betragen kann, dessen Anwendungsgebiet sehr begrenzen wird.

Ferrozement

Das Engineering Department der University of San Carlos in Guatemala hat in verschiedenen Anwendungsbereichen von Ferrozement Untersuchungen angestellt. Eine davon ist ein gebogenes Dachelement, ca. 2 m breit, mit einer Spannweite von über 3 m ohne Zwischenstützen, hauptsächlich für low-cost-Häuser mit Zementblock-Wänden. Das Material besteht aus 1 Teil Zement und 2 Teilen zermahlenem Bimsstein, mit zwei Lagen 22er Maschendraht verstärkt. Die Stärke ist ca. 2,5 cm.

Neues Asbestzement-Produkt

Vom guatemaltekischen Asbestzement-Hersteller wurde ein neues Produkt auf dem örtlichen Markt eingeführt. Es ist ein Dachdeckungspaneel (0,745 x 1,18 m) mit abwechselnd flacher und konvex geformter Oberfläche, entsprechend den Abmessungen der Tonziegeldeckung. Das Gewicht ist ca. 12,5 kg/m^2, und die Paneele werden auf einer Holzunterkonstruktion genau wie die herkömmlichen Asbestzement-Platten angebracht.
Der augenblickliche Preis beträgt 8.19 ₡/m^2. Der Hersteller bietet ebenfalls rote Farbe zu einem Preis von 9.80 ₡/Gallone (ca. 3,8 dm^3) an, so daß der Hausbesitzer damit ein Dach erhält, das dem Lehmziegeldach sehr ähnlich sieht. Unter Berücksichtigung von zwei Schichten Farbe entstehen Materialkosten von 8.97 ₡/m^2.

Zement-Faser-Wellplatten

In Honduras werden von A.I.D. unterstützte Feldversuche durchgeführt mit Zement-Faser-Wellplatten, welche mit einfacher Ausrüstung in den Dörfern hergestellt werden. Die Technologie ist ähnlich derjenigen, die vom Intermediate Technology Materials Workshop of the J.P.M. Penny & Associates Ltd. in England entwickelt wurde (s.4.2.2).

asphalt, and is offered in three colors: black, red and silver. The panels are corrugated and have overall dimensions similar to those of galvanized steel sheets. The weight is approximately 4 kg/m^2, and the material can be installed in the same manner as galvanized steel.
The price is lower than the competitive product (₡ 1.50/m^2), and the new material has gained some public acceptance, especially in coastal areas where rusting of the galvanized steel roofs is a problem. The effect of exposure to sun and rain, however, tends to cause flattening and distortion of the corrugations. Also, the material lacks fire resistance. Due to these deficiencies, use of the new material by the National Housing Institute has been discontinued.

Cement-stone Roofing

Another private industry in Costa Rica is developing a corrugated roofing panel, TECON, which reportedly is made of cement and pulverized stone without any other type of reinforcement. Some preliminary testing of this product conducted by the Materials Laboratory of Costa Rica's Housing Institute has shown some promising results; however, Institute personnel feel that the material's excessive weight, which may be as high as 37 kg/m^2, will greatly limit its field of application.

Ferrocement

The Engineering Department of the University of San Carlos in Guatemala has been conducting experiments on various ferrocement applications. One of these is a curved roofing element, about 2 m wide, designed to cover a 3 m span without intermediate supports, principally for low cost home with cement block wall construction. The material consists of 1 part cement to 2 parts crushed pumice reinforced with 2 layers of 22 gauge wire mesh. The thickness is approximately 2.5 cm.

New Asbestos-cement Product

A new product has been introduced in the lokal market by the Guatemalan asbestos-cement manufacturer. This is a roofing panel (0.745 x 1.18 m) especially formed with convex curved surface undulations which duplicate the dimensions of clay tile. The weight is about 12.5 kg/m^2, and the product is installed over a wooden frame in the same manner as conventional asbestos-cement sheets.
The current price is ₡ 8.19/m^2. The manufacturer also offers red paint at a price of ₡ 9.80/gallon so the homeowner can obtain a roof which more closely resembles clay tile. Considering the use of two coats of paint, this would increase the total material cost per square meter to ₡ 8.97.

Cement-fibre

In Honduras, field testing sponsored by AID has been initiated with cement-fibre corrugated roofing panels which are fabricated with simple equipment in rural villages. The technology used is similar to that developed by the Intermediate Technology Materials Workshop of the J.P.M. Parry & Associates Ltd., in England (see 4.2.2).

6. MÖGLICHE NEUENTWICKLUNGEN FÜR ZENTRALAMERIKA

6.1 Auswahl von Materialien für Vortests

Wie in vorhergehenden Abschnitten dieses Reports erwähnt, machen drei Typen von Dachdeckungssystemen über 90% aller Hausdächer in Zentralamerika aus. Diese schließen traditionelle Materialien (Tondachziegel und Stroh) und industriell hergestelltes verzinktes Stahlblech ein. Die Beliebtheit der traditionellen Dachdeckungssysteme scheint jedoch abzunehmen, möglicherweise aus folgenden Gründen:

- Das Strohdach, das hauptsächlich wegen seiner niedrigen Kosten Verwendung findet, wird von den örtlichen Einwohnern als weniger wünschenswert angesehen als andere Alternativen, was hauptsächlich seiner Neigung zur Insekten- und Ungeziefer-Einnistung zuzuschreiben ist. Auch erfordert seine Anbringung einiges handwerkliches Geschick, und es scheint, als ob in jeder folgenden Generation immer weniger Leute in der Loge seien, diese Arbeit auszuführen.
- Obwohl die Erscheinungsform des Tonziegeldoches von der örtlichen Bevölkerung geschätzt wird, ist dieses System wegen der kürzlichen Kostenerhöhung für Tonziegel für viele der Armen auf dem Lande viel zu teuer. Außerdem hat sich dieses Material bei Erdbeben als gefährlich erwiesen.

Das Dach aus verzinktem Stahl, das immer mehr die traditionellen Systeme ersetzt, ist die billigste zur Verfügung stehende Alternative, obwohl sogar dieser Preis für einige Landbewohner zu hoch ist, die weiterhin die Strohdachdeckung ausführen. Diese Dachdeckungsart ist aufgrund ihrer bereits in diesem Report erwähnten Unzulänglichkeiten weit davon entfernt, optimal zu sein, und ihr hoher Anwendungsfaktor zeigt nur, daß es keine andere gleichwertige Alternative gibt.

Aufgrund der oben beschriebenen Situation wurde beschlossen, eine Reihe von Voruntersuchungen durchzuführen, um die Möglichkeiten zur Entwicklung alternativer Dachdeckungssysteme auszuwerten, welche vom "do-it-yourself"-Bauherrn mit niedrigem Einkommen angewandt werden könnten, der gegenwärtig entweder verzinkten Stahl oder herkömmliche Dachdeckungsmaterialien verwendet. Um erfolgreich zu sein, sollte ein neues Dachdeckungssystem dieser Art einfacher anzubringen sein als Stroh, billiger als verzinkter Stahl, frei von Insekten- oder Ungezieferbefall, bedeutend geringeres Gewicht haben als Tondachziegel und bei Erdbeben keine Gefahrenquelle bieten.

Auch muß das Dachdeckungssystem angemessene Stabilität und Lebensdauer besitzen und sollte so weit wie möglich mit den Eigenschaften eines idealen Daches übereinstimmen, die in Abschnitt 7.2 dieses Reports angeführt sind. Um von der Bevölkerung besser akzeptiert zu werden, sollte es wie ein Wellblech- oder Tonziegeldach aussehen und, da dieses Projekt hauptsächlich auf die arme Landbevölkerung abgestimmt ist, sollten Materialien verwendet werden, die entweder auf dem Feld aufgesammelt oder einfach auf den örtlichen Märkten gekauft werden können.

In Anbetracht der oben genannten Kriterien wurde beschlossen, mit den folgenden Materialien zu experimentieren:

6. POSSIBLE NEW APPLICATIONS FOR CENTRAL AMERICA

6.1 Selection of Materials for Preliminary Testing

As indicated in previous sections of this report, three types of roofing systems account for over 90% of all house roofs in Central America. These include the traditional materials (clay tile and thatch) and industrially manufactured galvanized steel sheets. The popularity of the traditional roofing systems, however, appears to be diminishing, possibly due to the following reasons:

- The thatched roof, used principally because of its low cost, is considered less desirable than other alternatives by local inhabitants, due mainly to its tendency to become infested with insects and rodents. Also, its installation requires some manual skill, and it appears that fewer people in each succeeding generation are capable of performing this task.
- Although the appearance of the clay tile roof is esteemed by the local population, recent clay tile cost increases have resulted in this system being far too expensive for many of the rural poor. In addition, this material has been proven hazardous during earthquakes.

The galvanized steel roof which is tending to substitute the traditional systems is the lowest cost available alternative, although even this cost is too high for some rural inhabitants who continue to use thatch. This type of roofing system, due to the deficiencies discussed previously in this report, is far from optimum, and its high usage in Central America may simply reflect the lack of any other alternative.

In view of the above, it was decided to conduct a series of preliminary tests designed to evaluate the possibilities for developing alternative roofing systems which could be used by the low income "do-it-yourself" home builder, who currently uses either galvanized steel or traditional roofing materials. To be successful, a new roofing system of this type should be simpler to install than thatch, lower cost than galvanized steel, free from insect or rodent infestation, significantly lighter weight than clay tile and should present no earthquake hazard.

Also, the roofing system must have adequate strength and life, and should conform as much as possible with the characteristics of an ideal roof, which are listed in Section 7.2 of this report. Its appearance should tend to simulate the clay tile roof for better acceptability by the local population and, since this project is oriented principally towards the rural poor, materials should be used which can either be gathered in the field or easily purchased in local markets.

Taking the above criteria into consideration, it was decided to experiment with the following materials:

A. Hauptmaterial.
Mit Kalk stabilisierte Erde und mit Bims oder Sand vermischter Zement wurden als hauptsächlichste Dachdeckungsmaterialien ausgewählt, da sie in ganz Zentralamerika ohne weiteres verfügbar sind und bereits in der Bauindustrie Verwendung finden. Von den beiden Alternativen wäre stabilisierte Erde aus Kostengründen vorzuziehen, aber dieses Material ist bisher ausschließlich in Blöcken zum Bau von Wänden verwendet und noch nicht für die Anwendung als Dachdeckung ausgewertet worden. Zementmischungen könnten deshalb erforderlich werden, falls angemessene Festigkeiten mit stabilisierten Erden nicht erreicht werden können.

B. Bewehrungsmittel.
Die folgenden drei Materialarten wurden zur Verstärkung des Dachdeckungsmaterials in Betracht gezogen:

1. Natürliche Fasermaterialien, wie sie in vielen Gegenden Zentralamerikas vorzufinden sind, einschließlich Sisalfasern (die gegenwärtig zur örtlichen Herstellung von Säcken verwendet werden), Piniennadeln, Stroh und Kokosnußfasern.

2. Örtlich hergestellte Gewebe.
Jute- und Sisalsäcke, die in Zentralamerika hauptsächlich für Kaffeebohnen-Verpackung verwendet werden, und preiswerter Baumwollstoff, der in Guatemala hergestellt wird, wurden als Verstärkungsmaterialien ausgewertet.

A. Principal Material.
Lime-stabilized soil and cement mixed with pumice or sand were selected as the principal roof covering materials; since they are readily available throughout Central America and already are used in the construction industry. Of the two alternatives, stabilized soil would be preferable for cost reasons, but this material so far has been used exclusively in blocks for wall construction and has not been evaluated for roofing applications. Cement mixes, therefore, might be required in case adequate physical strength cannot be obtained with stabilized soil systems.

B. Reinforcement.
The following three types of materials were considered for reinforcement of the principal roof covering material:

1. Natural fibrous materials available in many areas in Central America, including sisal fibres currently used for the local manufacture of sacks, pine needles, straw and coconut fibres.

2. Locally produced fabrics.
Jute and sisal sacks used principally in Central America for coffee beans, and inexpensive cotton cloth produced in Guatemala were evaluated as reinforcing materials.

6.1

6.2

3. Maschendraht.
Draht wird in allen zentralamerikanischen Ländern produziert, und die gebräuchlichsten Drahterzeugnisse werden örtlich hergestellt. Hühnermaschendraht wurde als mögliches Verstärkungsmaterial in Betracht gezogen, jedoch als Alternative geringerer Priorität wegen seiner verhältnismäßig hohen Kosten.

C. Oberflächenschutz.
Als Oberflächenschutz für stabilisierte Erd-Dachdeckungen wurde sowohl Kalkanstrich als auch Bitumen in Erwägung gezogen. Da Kalk in den ländlichen Gebieten ganz Zentralamerikas hergestellt wird, sollte dieser Alternative, wenn sie erfolgreich ist, der Vorzug gegeben werden vor importierten Bitumenprodukten.

D. Unterkonstruktion.
Bei den Vorversuchen sollte der Gebrauch von teuren Pinienholz-Tragsystemen vermieden und die Möglichkeiten der Verwendung von Bambus oder bambusähnlichem Rohr, kombiniert mit örtlich hergestelltem Seil oder Schnur, untersucht werden. Zusätzlich zu dem Kostenvorteil für den Selbsthilfe-Hausbauer wurde angestrebt, die Unterkonstruktion so zu gestalten, daß die Dachdeckung eine Wellenform erhält und somit das Aussehen eines Wellplatten- oder Tonziegeldaches simuliert.

Die in diesen Experimenten ausgewerteten Materialien, die auf dem Feld (Hochland von Guatemala) kostenlos zur Verfügung standen, waren folgende:

Abb. 6.1 Caña de castilla, ein reichlich vorhandenes und leicht ersetzbares (schnell wachsendes) Rohmaterial.

Fig. 6.1 Caña de castilla, an abundant and easily renewable raw material.

Abb. 6.2 Pajón (Epicampes macroura).
Fig. 6.2 Pajón (Epicampes macroura).

Abb. 6.3 Erdprobe für Laborversuche, entnommen 50 cm unterhalb der Oberfläche, um Humus und organische Stoffe zu eliminieren.

Fig. 6.3 Soil samples for testing, taken from 50 cm below ground surface to eliminate humus and organic matter.

3. Wire mesh
Wire is drawn in all of the Central American countries, and most common wire products are produced locally. Chicken wire was considered as a possible reinforcing material, but as a low priority alternative due to its relatively high cost.

C. Surface Protection.
For surface protection of stabilized soil roof coverings, both lime slurry and bitumen were considered. Since lime is produced in rural areas throughout Central America, this alternative, if successful, would be preferable to the use of imported bituminous products.

D. Support System.
For the preliminary experiments, it was decided to avoid the use of high cost pine lumber support systems, and to concentrate efforts on the use of bamboo or bamboo-like canes combined with locally produced rope or twine. In addition to the cost advantage to the self-help home builder, it was felt that this type of support system could be designed in such a way as to give a corrugated effect of the roof covering, thereby tending to simulate the appearance of clay tile.

The materials evaluated in these experiments, which were obtained in the field (Guatemala highlands) without cost, were the following:

- Erde (verschiedene Proben aus verschiedenen Gegenden)
- Sand und gemahlener Bims
- Kokosnußfasern (von Schalen)
- Stroh (pajón)
- Piniennadein
- Bambus
- Caña de Castilla (bambusähnliches Rohr)

Nachstehend die gekauften Materialien und ihre Einheitspreise:

Material	Einheit	Einheitspreis
Portlandzement	kg	$ 0.08
Löschkalk	kg	$ 0.07
ungelöschter Kalk	kg	$ 0.05
Sisal- und Jute-Sackmaterial	m^2	$ 1.09
Baumwolltuch	m^2	$ 0.61
Hühnermaschendraht	m^2	$ 1.37
Seil	lfdm	$ 0.08
Bindfaden	lfdm	$ 0.01
Asphalt	Liter	$ 1.62
Verdünnungsmittel	Liter	$ 0.20

Es sollte erwähnt werden, daß zusätzlich zu den Experimenten mit den oben genannten Materialien, die im nächsten Abschnitt 6.2 erläutert werden, zu Beginn drei andere Versuche initiiert, später jedoch außer Erwägung gelassen wurden. Es folgt eine kurze Beschreibung:

1. Grasdach. (Siehe Abb. 6.14, Seite 134)
   Aus Bambusstützen, die mit Bindfaden zusammengebunden und mit Plastikfolie bedeckt waren, wurde ein kleines Prototyp-Dach gebaut. Eine Dachdeckung aus Baumwollsäcken, die mit Erde und Grassamen gefüllt waren, wurde dann über die Plastikfolie gelegt und am Stützrahmen festgebunden. Man hoffte, daß das Gras durch das Baumwollmaterial wachsen und schließlich eine homogene Masse bilden würde, die von dem Wurzelsystem der Gräser zusammengehalten wird. In der Praxis stellte sich heraus, daß, obwohl der Grassamen aufging und an einigen Stellen durch die Baumwollsäcke wuchs, weiteres Wachstum stagnierte und nicht ausreichte, den Rest des Daches zu bedecken. Auch erschien das Gewicht pro Flächeneinheit für dieses System extrem hoch. Der Versuch wurde als Mißerfolg angesehen, und weitere Arbeit auf diesem Gebiet wird nicht empfohlen.

2. Asphaltbestrichenes Stroh. (Siehe Abb. 6.10/6.11, Seite 133)
   Es wurde ein Prototyp-Dachsystem vorbereitet, das aus Stroh (pajón) bestand und auf welches Asphaltemulsion aufgebürstet wurde, und welches an eine Holz- und Hühnerdraht-Unterkonstruktion angebunden wurde. Dieses Experiment wurde durchgeführt, um die Möglichkeit der Verbesserung von bestehenden traditionellen Strohdächern zu untersuchen. Es stellte sich jedoch heraus, daß der für eine angemessene Oberflächenabdeckung benötigte Asphalt (ca. 1 Gallone/m^2) Materialkosten

- Soil (various samples from different areas)
- Sand and crushed pumice
- Coconut fibres (from husks)
- Straw (pajón)
- Pine needles
- Bamboo
- Caña de Castilla (bamboo-like cane)

The purchased materials and their unit costs were as follows:

Material	Unit	Cost/Unit
Portland cement	kg	$ 0.08
Hydrated lime	kg	$ 0.07
Quicklime	kg	$ 0.05
Sisal and jute sacking	m^2	$ 1.09
Cotton cloth	m^2	$ 0.61
Chicken wire	m^2	$ 1.37
Rope	lin.m	$ 0.08
Twine	lin.m	$ 0.01
Asphalt	liter	$ 1.62
Solvent	liter	$ 0.20

It should be mentioned that, in addition to the experiments with the above materials which are discussed in the next sub-section 6.2, three other trials were initiated early in the testing program, but were later dropped from consideration. A brief description of each follows:

1. Grass Roof. (See Fig. 6.14, page 134)
   A small prototype roof support system was constructed using bambao support members tied together with twine and covered with a polyethylene sheet. A roof covering consisting of cotton bags containing earth and grass seed was then placed over the plastic sheet and tied to the support frame. It was hoped that the grass would grow through the cotton fabric and eventually form a continuous mass held together by the grass root system. In practice, it was found that although the grass seed did germinate and grow through the cotton bags in some areas, later growth was stunted and did not propogate sufficiently to cover the rest of the roof. Also, the weight per unit area appeared excessive for this system.
   This trial was considered a failure and no further work in this area is recommended.

2. Asphalt-coated Thatch. (See Fig. 6.10/6.11, page 133)
   A prototype roof system was prepared consisting of thatch (pajón straw) brush-coated with asphalt emulsion, and tied to a wood and chicken wire support system. This experiment was conducted with a view towards evaluating the possibility of improving present traditional thatched roofs. However, it was found that the amount of asphalt required to obtain a reasonable surface covering (about 1 gallon/m^2) represented a material cost considerably greater than that required for a galvanized steel roof. This idea, therefore, was dropped for economic reasons.

verursachte, die beträchtlich über denjenigen für ein Dach aus verzinktem Stahl lagen. Diese Idee wurde deshalb aus wirtschaftlichen Gründen aufgegeben.

3. Chemische Imprägnierungszusätze. (Siehe Abb. 6.12/6.13, Seite 134)
Chemische Materialien (CONSERVEX und CONSOLID 444), die speziell für die Erdverfestigung von der Consolid AG, CH-9435 Heerbrugg S 6, Aechelistraße 18, Schweiz, hergestellt wurden, wurden zu Beginn des Programms als Zusätze für Dachdeckung aus stabilisierter Erde getestet. Zusatzmittelbeimengungen von einem Volumenteil CONSERVEX zu hundert und einem Volumenteil CONSOLID 444 zu tausend Volumenteilen Erd-Kalkmischung wurden gegen eine unbehandelte Erd-Kalkmischung getestet. Vom technischen Standpunkt waren die Ergebnisse recht vielversprechend, da die behandelte Probe gegenüber der unbehandelten bei den Laboruntersuchungen über Wasseraufnahme-Eigenschaften (35 ml/cm^2 gegen 45 für die Kontrolle) und ebenfalls, als es der Witterung ausgesetzt wurde, viel größere Widerstandsfähigkeit gegen Erosion aufwies.
Diese Chemikalien sind jedoch importierte Erzeugnisse und verhältnismäßig teuer (ca. 1.00 $/Liter CONSERVEX und 4.00 $/Liter CONSOLID 444). Sie werden wahrscheinlich hauptsächlich an öffentliche Bauträger und an private Baufirmen verkauft werden; ihre leichte Verfügbarkeit für den Landbewohner, der auf dem örtlichen Markt einkauft, ist zu bezweifeln. Deshalb wurde trotz der Vorteile der Chemikalien beschlossen, keine weiteren Experimente mit diesen Materialien durchzuführen, es sei denn, daß spätere Tests zeigen, daß ihre Anwendung von Bedeutung ist.

6.2 Vorbereitung und Erprobung von Prototyp - Bedachungssystemen

Wegen knapper Zeit und Ressourcen des vorliegenden Projektes konnten nur sehr unverbindliche Experimente durchgeführt werden. Das Ziel war, so viele Ideen und verschiedene Materialien wie möglich auszuprobieren, um diejenigen herauszukristallisieren, die zukünftige weitergehende Experimente rechtfertigen. Sowohl Testtafeln als auch komplexe Prototyp-Dachdeckungssysteme wurden von Hand gefertigt, unter Zuhilfenahme von nur wenigen einfachen Werkzeugen und Einrichtungen, um mehr mit den Methoden übereinzustimmen, die wahrscheinlich von einem Hausbauer mit niedrigem Einkommen in Zentralamerika angewendet werden.

6.2.1 Testtafeln

Für die erste Testserie wurden einfache Testtafeln angefertigt, um eine Auswertung der relativen Stärke von Kalk-stabilisierter Erde und Zement-Bims oder Zement-Sand-Mischungen zu ermöglichen und um eine Vor-Auswahl aus einer Anzahl möglicher Bewehrungsmaterialien zu treffen.

Die Tafeln (10 x 10 x 1,2 cm) wurden handgefertigt, indem mit einer Kelle die Mischung in eine Holzform gegeben und kompaktiert wurde. Erde, Sand und Bims wurden gesiebt, um Fremdmaterial zu entfernen; die trockenen Mischungszutaten wurden

3. Chemical Waterproofing Additives. (See Fig. 6.12/6.13, page 134)
Chemical materials (CONSERVEX and CONSOLID 444) manufactured especially for soil consolidation by Consolid AG, CH-9435 Heerbrugg S6, Aechelistraße 18, Switzerland, were tested early in the program as additives for stabilized soil roof coverings. One part per hundred by volume of CONSERVEX and one part per thousand of CONSOLID 444 were incorporated into a lime-stabilized soil sample and tested against an untreated control. From a technical standpoint results were quite promising, since the treated sample was superior to the control in laboratory water absorption tests (35 ml/cm^2 vs 45 for the control) and when exposed to the elements showed very significantly greater resistance to erosion.
These chemicals, however, are imported products and relatively high priced (approximately $ 1.00 per liter for CONSERVEX and $ 4.00/liter for CONSOLID 444). They will probably be sold principally to national institutions active in construction, and to private construction firms; their ready availability to the rural inhabitant who shops in local markets is doubtful. Therefore, despite the beneficial effect of the chemicals, it was decided not to conduct further experiments with these materials unless future testing shows their use to be essential.

6.2 Preparation and Testing of Prototype Samples

Due to time and resource limitations of the present project, only experiments of a very preliminary nature could be effected. The purpose of these was to screen as many ideas and material variations as possible in order to identify those which merit more detailed experimentation in the future. Both test plaques and more complex prototype roofing systems were prepared by hand, using only a few simple tools and fixtures in order to conform more closely with the methods that probably would be used by a low-income home builder in Central America.

6.2.1 Test Plaques

For the first series of tests, simple test plaques were prepared to permit an evaluation of the relative strength of lime stabilized soil and cement-pumice or sand mixtures, and to effect a preliminary screening of a number of possible reinforcing materials.

The plaques were hand made, trowelling the mixture into a wooden form designed for a plaque size of 10 x 10 x 1.2 cm. The soil, sand and pumice were screened to eliminate extraneous material; the dry mix ingredients were measured by volume and

nach Volumen bemessen und handgemischt. Es wurde nur so viel Wasser hinzugefügt, wie es die leichte Handhabung mit der Kelle erforderte. Die Stroh- und Piniennadel-Bewehrungen wurden auf ungefähr 3 cm Länge geschnitten und der nassen Mischung beigegeben. Gewebe- und Maschendraht-Verstärkungen wurden mit Scheren auf die erforderliche Größe zugeschnitten und über die erste Schicht der Mischung in der Holzform gelegt.

Diese erste Testreihe wurde durchgeführt, um eine grobe Auswertung der folgenden Variablen zu ermöglichen:

- Erden.
  Es lagen drei Bodenproben von verschiedenen Gegenden aus dem Hochland von Guatemala vor (Antigua, San Lucas und El Tejar). Es wurden alleine durch visuelle Prüfung diejenigen Erden ausgewählt, die den Anschein für die richtige Zusammensetzung zum Formen hatten.
- Kalk.
  Sowohl Löschkolk, der in Guatemala industriell angefertigt wird, als auch ungelöschter Kalk, der in kleinen ländlichen Kalkbrennereien hergestellt wird, wurde in 5 und 10%igen Beimengungen mit den Bodenproben trocken vermischt.
- Zementmischungen.
  Für Prüfzwecke wurden drei Zementmischungen verwendet: Zement-Bims (1 : 1), Zement-Bims (1 : 4) und Zement-Sand (1 : 4).
- Bewehrungsmaterialien.
  Als Bewehrungen wurden Baumwollgewebe, Jute- und Sisalsäcke, Maschendraht, Sisalfaser, Piniennadeln und Stroh ausgewertet.

Wie aus den nachfolgenden Tabellen ersichtlich, wurden 36 Tafeln mit stabilisierten Erdproben und 15 mit Zementmischungen hergestellt.

hand mixed. Only enough water to permit easy trowelling was added. The straw and pine needle reinforcing materials were cut to approximately 3 cm lengths and incorporated into the wet mix. Fabric and wire mesh reinforcements were precut to size with scissors, and were placed over the first layer of mixture trowelled into the wooden form.

This initial test series was designed to permit a preliminary evaluation of the following variables:

- Soils.
  Three soil samples were obtained from different locations in the Guatemala highlands (Antigua, San Lucas and El Tejar). Soils were selected which appeared, through visual inspection only, to have an adequate consistency for molding.
- Lime Stabilizer.
  Both hydrated lime industrially manufactured in Guatemala, and quicklime produced in small rural kilns were dry blended with the soil samples in 5 to 10 % concentrations.
- Cement Mixes.
  For control purposes, three cement mixes were prepared: cement pumice (1 : 1 ratio), cement-pumice (1 : 4) and cement-sand (1 : 4).
- Reinforcement.
  The reinforcing materials evaluated included cotton fabric, jute and sisal sacks, wire mesh, sisal fibre, pine needles and straw.

As shown in the following table, 36 plaques were prepared with stabilized soil samples, and 15 with cement mixes.

ERSTE SERIE TEST-TAFELN, HERGESTELLT 18. - 20. JUNI 1979

A. Stabilisierte Erden

Tafel Nr.	Erdprobe aus	Bindemittel	Bewehrung
1	Antigua	5% Löschkalk	Keine
2	Antigua	5% Löschkalk	Baumwollgewebe (1 Lage)
3	Antigua	5% Löschkalk	Baumwollgewebe (2 Lagen)

31	El Tejar	10% hydrated lime	Chicken wire (2 layers)
32	San Lucas	5% quicklime	None
33	San Lucas	5% quicklime	Cotton fabric (1 layer)
34	San Lucas	5% quicklime	Chicken wire (1 layer)
35	San Lucas	5% quicklime	Sisal fibre
36	San Lucas	5% quicklime	Pine needles

B. Zementmischungen

Tafel Nr.	Mischungsverhältnis		Bewehrung
1	Zement - Bims	1 : 1	Keine
2	Zement - Bims	1 : 1	Sisalfaser
3	Zement - Bims	1 : 1	Baumwollgewebe (1 Lage)
4	Zement - Bims	1 : 1	Hühnerdraht (1 Lage)
5	Zement - Bims	1 : 1	Piniennadeln
6	Zement - Bims	1 : 4	Keine
7	Zement - Bims	1 : 4	Sisalfaser
8	Zement - Bims	1 : 4	Piniennadeln
9	Zement - Bims	1 : 4	Baumwollgewebe (1 Lage)
10	Zement - Bims	1 : 4	Hühnerdraht (1 Lage)
11	Zement - Sand	1 : 4	Keine
12	Zement - Sand	1 : 4	Sisalfaser
13	Zement - Sand	1 : 4	Baumwollgewebe (1 Lage)
14	Zement - Sand	1 : 4	Hühnerdraht (1 Lage)
15	Zement - Sand	1 : 4	Piniennadeln

Alle Tafeln konnten im Freien, geschützt vor Witterungseinflüssen, unter einer durchsichtigen Kunststoffolie zwei Wochen lang austrocknen, wonach die Tafeln durch leichtes Klopfen per Hand auf einer harten Fläche auf ihre Festigkeiten in Relation zu den verschiedenen Materialzusammensetzungen hin getestet wurden. Die Ergebnisse dieses einfachen Testvorgangs zeigten, daß die Stärke der Zementmischungen klar überlegen war; sie überstanden den Test ohne Probleme. Alle Tafeln aus stabilisierter Erde brachen leicht auseinander, und es konnte kein wesentlicher Unterschied zwischen Erdsorten, Kalk-Konzentrationen oder der Art des verwendeten Kalks festgestellt werden.

Was die Bewehrungen betraf, wurde folgendes beobachtet:

- Obwohl Stroh und Piniennadeln als Verstärkung für stabilisierte Erdblöcke benützt worden sind, erscheinen diese Materialien viel zu grob für die dünnen Materialquerschnitte bei der Dachdeckung, und sie neigen dazu, die Stabilität insgesamt zu beeinträchtigen. Weitere Experimente mit diesen Materialien werden nicht empfohlen.
- Sisalfaser, die viel feiner ist als die oben genannten Materialien, scheinen für diese Anwendung geeignet zu sein.
- Mit den Jute- und Sisalsäcken entstanden Probleme beim Zuschneiden auf Tafelgröße wegen des Ausfransens der zugeschnittenen Teile und auch beim Verdichten wegen der fehlenden Adhäsion zwischen Gewebe und Mischung. Deshalb wurden mit diesen Verstärkungsmaterialien nur zwei Tafeln angefertigt. Ihre Eignung als Bewehrungen wird jedoch bei großflächigen Versuchsplatten weiterhin untersucht werden.

B. Cement Mixes

Sample No.	Proportion of Mix		Reinforcement
1	Cement - pumice	1 : 1	None
2	Cement - pumice	1 : 1	Sisal fibre
3	Cement - pumice	1 : 1	Cotton fabric (1 layer)
4	Cement - pumice	1 : 1	Chicken wire (1 layer)
5	Cement - pumice	1 : 1	Pine needles
6	Cement - pumice	1 : 4	None
7	Cement - pumice	1 : 4	Sisal fibre
8	Cement - pumice	1 : 4	Pine needles
9	Cement - pumice	1 : 4	Cotton fabric (1 layer)
10	Cement - pumice	1 : 4	Chicken wire (1 layer)
11	Cement - sand	1 : 4	None
12	Cement - sand	1 : 4	Sisal fibre
13	Cement - sand	1 : 4	Cotton fabric (1 layer)
14	Cement - sand	1 : 4	Chicken wire (1 layer)
15	Cement - sand	1 : 4	Pine needles

All plaques, protected from the elements by a polyethylene cover, were allowed to cure for a period of two weeks, at which time each plaque was hand tapped against a hard surface in an attempt to establish relative strengths of the different variable combinations. The results of this simple testing procedure showed a clear superiority strengthwise for the cement-mixes which stood up to testing without failure. All of the stabilized soil plaques broke apart quite easily, and no significant differences could be detected between soils, lime concentrations or the type of lime used.

As far as the reinforcing materials were concerned, the following observations were made:

- Although straw and pine needles have been used as reinforcement for stabilized soil building blocks, these materials appear far too coarse for the thin sections involved in roofing applications, and tend to weaken overall structural strength. Further experimentation with these materials will not be recommended.
- Sisal fibre, much finer than the above materials, appears suitable for this application.
- Problems were encountered with jute and sisal sacking materials when cut to plaque size, due to unravelling and packing of the cut sections. For this reason, only two plaques were prepared with these reinforcing materials. However, their use will be further evaluated in larger size prototype samples.

Abb. 6.4 Erd-Kalk-Probetafeln (10 x 10 cm), jede mit unterschiedlichem Kalkanteil und verschiedener Bewehrung, zur Aushärtung in der Sonne aufgestellt, unter einer durchsichtigen Kunststoffolienabdeckung.

Fig. 6.4 Soil-lime samples, 10 cm square, each having different percentages of lime and varying reinforcements, placed in the sun for curing under a transparent polythene sheet.

Abb. 6.5 Einige willkürlich zusammengestellte Erd-Kalk-Probetafeln, offen im Freien aufgestellt, nach dreimonatiger Aushärtung unter Folienabdeckung oder im Innenraum. (Anmerkung: Obwohl die Schlagfestigkeit nach zwei Wochen Aushärtung bei allen Proben gleich schlecht war, zeigte die Außenerprobung große Unterschiede im Witterungsverhalten, was offensichtlich auf den unterschiedlichen Tongehalt der Erdproben zurückzuführen ist).

Fig. 6.5 Some of the soil-lime samples, chosen at random, exposure tested after three months of hardening under cover or indoors. (Note: although impact resistance after two weeks curing was equally poor on all samples, the exposure test showed greatly differing material qualities on account of varying clay contents of the soil samples.

- Obwohl Baumwolltuch ein gutes Verstärkungsmaterial zu sein scheint, wurde es als schwierig empfunden, gute Haftung zwischen dem Gewebe und der stabilisierten Erde zu erreichen. Dies kann auf die verhältnismäßig trockene Mischung, die verwendet wurde, zurückzuführen sein, und es sollten weitere Erprobungen dieses Materials mit feuchteren Mischungen durchgeführt werden.
- Hühnerdraht ist ein gutes Verstärkungsmaterial, er wird jedoch, wie bereits in vorhergehenden Abschnitten erwähnt, wegen seiner höheren Kosten als Alternative mit geringerer Priorität betrachtet.

Da bei visueller Überprüfung der zerbrochenen stabilisierten Erdtafeln sich einige Absonderungen zeigten, wurde eine zweite Serie von 7 Tafeln angefertigt in der gleichen Art wie die vorhergehenden, außer daß das Handmischen der trockenen Zutaten sorgfältiger durchgeführt wurde. Es wurde eine neue Bodenprobe aus San Augustin, Guatemala, verwendet mit Kokosnußfaser als Verstärkung zusätzlich zu den Materialien, die in der ersten Testreihe vielversprechend zu sein schienen. Sämtliche Proben enthielten 10% Löschkalk als Stabilisierung; die Verstärkungsmaterialien waren folgende:

Probe	Verstärkung
1	keine
2	keine
3	Sisalfaser
4	Hühnerdraht (1 Schicht)
5	Baumwollgewebe (2 Schichten)
6	Kokosnußfaser (trocken)
7	Kokosnußfaser (vorgeweicht)

Nach der zweiwöchigen Austrocknungsperiode wurden die Tafeln mit der gleichen Methode, wie sie für die frühere Testreihe angewandt wurde, auf ihre Stärke hin geprüft. Die Ergebnisse waren identisch, da jede Tafel leicht gebrochen werden konnte, wenn sie gegen eine harte Unterlage gestoßen wurde. Die Kokosnußfaser schien als Verstärkungsmaterial der Sisalfaser ähnlich zu sein.

In Anbetracht der klaren Überlegenheit bei den Tafel-Tests der Zement-Sand- oder Bims-Mischungen im Vergleich mit stabilisierter Erde wurde beschlossen, die Bemühungen auf dieses Material zu konzentrieren bei der Herstellung von Prototyp-Dachdeckungssystemen. Weitere Versuche mit stabilisierter Erde werden jedoch wegen des offensichtlichen wirtschaftlichen Vorteils für den Verbraucher fortgesetzt werden, wenn es gelingt, die physikalischen Merkmale dieses Materials genügend zu verbessern, um eine angemessene Festigkeit für die Anwendung als Dachdeckung zu erreichen.

In der letzten Phase des Projekts, nach Beendigung der Prototyp-Dachdeckungs-Versuche, wurden einige der zerbrochenen stabilisierten Erd-Tafeln, die willkürlich ausgewählt wurden, während starker Regenzeit der Witterung ausgesetzt. Dieser Test zeigte, daß nach 2 1/2 Monaten Aushärtung (nach den Klopftests) Unterschiede in

- Although cotton fabric appears to be a good reinforcing material, it was found to be difficult to obtain good adhesion between the cloth and the stabilized soil. This may have been due to the relatively dry mixture being used, and future evaluation of this material with wetter mixes should be made.
- Chicken wire is a good reinforcing material, but, as mentioned in previous sections, is considered a low priority alternative due to its higher cost.

Since visual inspection of the broken stabilized soil plaques showed some evidence of lime segregation, a second series of 7 plaques was prepared in the same manner as the previous samples, except that more time and greater care was taken in hand mixing the dry ingredients. A new soil sample obtained in San Augustin, Guatemala, was used, and coconut fibres were evaluated as reinforcement in addition to the materials which appeared promising in the first series of tests. All samples contained 10% hydrated lime as the stabilizer; the reinforcing materials were as follows:

Sample	Reinforcement
1	None
2	None
3	Sisal fibre
4	Chicken wire (1 layer)
5	Cotton fabric (2 layers)
6	Coconut fibre (dry)
7	Coconut fibre (presoaked)

After the standard two week cure period, the plaques were tested for strength using the same procedure previously described for the first series of tests. Results were identical as each plaque could be easily broken when tapped against a hard surface. The coconut fibre appeared to be similar to sisal as a reinforcing material.

In view of the clear superiority shown in the plaque tests of the cement-sand or pumice mixes in comparison with stabilized soil, it was decided to concentrate efforts on this material in the preparation of prototype roofing systems. However, further experimentation with stabilized soil will be continued due to the obvious economic advantage to the consumer if the physical characteristics of this material can be improved sufficiently to reach acceptable strength levels for roofing applications.

After completion of the prototype roofing system experiments at the end of the present project, some of the broken stabilized soil plaques, selected at random, were exposed to the elements during a period of heavy rainfall. This exposure test showed differences between soil samples, after a 2 1/2 months cure period, which may be

den Proben festzustellen waren, was von großer Bedeutung sein kann. Die Tafeln aus El Tejar-Erde zeigten nach 24 Stunden schwere Auswaschungserscheinungen; etwas weniger Auswaschung wurde bei den Erdproben aus San Lucas bemerkt, und fast keine Auswaschungen gab es nach 1-monatiger Aussetzung bei den Proben aus Antigua-Erde. Dieses abschließende Experiment zeigt, daß sorgfältige Auswahl der Erde der wichtigste Faktor sein kann, um angemessene physikalische Stärke für stabilisierte Erd-Dachdeckungssysteme zu erhalten. Für weitere Programme wird deshalb empfohlen, eine Anzahl von Bodenproben auszuwählen, physikalischer und chemischer Analyse zu unterziehen und zu testen, welche Eigenschaften wesentlich sind. Diese Charakteristika sollten mit einfachen visuellen oder manuellen Tests feststellbar und in der Praxis von jedem einzelnen Hausbauer in Zentralamerika nachvollziehbar sein.

6.2.2 Prototyp-Bedachungssysteme

6.2.2.1 Verfahrensweise und Versuchsergebnisse

Erste Versuchsreihe

Für die erste Versuchsreihe für Dachdeckungssysteme wurde ein Befestigungsrahmen (45°-Neigung) aus Pinienholz hergestellt mit vier 1 m^2 großen offenen Flächen zum Bau von Prototyp-Dächern. Die erste dieser Flächen wurde für den Versuch mit asphalt-bestrichenem Stroh benützt, wie vorher in Absatz 6.1. beschrieben. Die anderen Experimente waren:

1-1 Mit Zement-Sand getränkte Säcke

Im zweiten Rahmenabschnitt wurde eine Tragkonstruktion aus drei in Fallrichtung verlaufenden Bambuspfählen, die in gleichem Abstand zueinander angeordnet waren, hergestellt. Statt Pfetten wurden horizontal verlaufende, um jeden Bambuspfahl gewickelte Seile befestigt. Der Abstand zwischen den Seilpfetten betrug im Durchschnitt 13 cm.
Gekaufte Sisalsäcke wurden in 30 x 50 cm große rechteckige Teile geschnitten und die Schnittkanten mit der Hand umgenäht, um ein Ausfransen zu vermeiden. Eine nasse Mischung aus einem Teil Zement und zwei Teilen Sand wurde hergestellt, und jeder Sack wurde in diese Mischung getaucht. Die imprägnierten Säcke wurden, noch naß und biegsam, sofort über die Stützenkonstruktion gelegt mit vertikalen und horizontalen Überlappungen von ca. 8 bis 10 cm.
Da die imprägnierten Säcke über die vertikalen Bambuspfähle gelegt wurden und mit den horizontalen Seilpfetten zurücksackten, wurde eine wellenförmige Wirkung erzielt, die einem Tonziegeldach etwas ähnlich sah. Die Säcke wurden von Hand an die Seilträger gebunden und ein Endanstrich aus nasser Zement-Sand-Mischung mit einer Bürste über die ganze Fläche aufgetragen. Nach einer einwöchigen Aushärtungszeit unter Dach wurde der Prototyp den Witterungseinflüssen ausgesetzt und erzielte ganz zufriedenstellende Ergebnisse. Aus dem Experiment gingen die folgenden Beobachtungen über diesen Dachdeckungstyp hervor:

very significant. Samples prepared with El Tejar soil showed very severe erosion after 24 hours exposure; somewhat less erosion was noted with the San Lucas soil samples, and almost no erosion occurred after one month exposure with the samples produced from Antigua soil. This final experiment indicates that proper soil selection may be the most important factor in obtaining adequate physical strength for stabilized-soil roofing systems. In future programs, therefore, it is recommended that a number of soil samples be selected, subjected to physical and chemical analyses, and tested to determine which characteristics are essential. These characteristics when determined should be correlated with simple visual or manual tests that could be carried out in the field by individual low-income home builders in Central America.

6.2.2 Prototype Roofing Systems

6.2.2.1 Preparation and Experimental Results

First Series

For the first series of roofing system experiments, an exposure deck (45° angle) was fabricated from pine lumber, with four one square meter open spaces available for the construction of prototype roofs. The first of these spaces was used for the asphalt-coated straw experiment discussed previously in Section 6.1. The other experiments were as follows:

1-1 Cement-sand Impregnated Sacks

A support structure was prepared with three equidistant vertical bamboo poles spanning the one meter space. Ropes looped around the bamboo poles and tied to the exposure deck frame were used as the horizontal support members. The spacing between the rope supports averaged about 13 cm.
Purchased sisal sacking was cut into 30 x 50 cm rectangular sections and the cut edges were hand sewn to prevent unravelling. A wet mixture of one part cement to two parts sand was prepared, and each sack was immersed in the mix. The impregnated sacks, still wet and flexible, were placed immediately over the support structure with vertical and horizontal overlaps of about 8 to 10 cm.
Since the impregnated sacks were laid over the vertical bamboo poles and allowed to sag against the horizontal rope supports, a corrugated effect was created somewhat similar to the appearance of a clay tile roof. The sacks were hand tied to the rope supports, and a final coat of wet cement-sand mixture was brushed over the entire prototype with a broom.
After a one week curing period under cover, the sample was exposed to the elements, with quite satisfactory results. The following observations concerning this type of roofing system resulted from the experiment:

Äußeres Erscheinungsbild

Obwohl die Oberfläche des imprägnierten Zementsacks ziemlich rauh war und viel mehr Arbeit darauf verwendet werden muß, um die Herstellungstechniken zu verbessern, war die Gesamterscheinung des Daches recht annehmbar. Seine Ähnlichkeit mit einem Tonziegeldach könnte die Chancen, von der Bevölkerung akzeptiert zu werden, erhöhen, besonders wenn der Mischung ein Pigment beigegeben werden könnte, um die rotbraune Farbe zu erzielen.

Aufbau

Probleme entstehen durch das übermäßige Absacken der Säcke zwischen den Seilträgern, und es scheint, als ob eine andere Art Unterkonstruktion entwikkelt werden sollte. Auch war es mühsam und zeitraubend, die Schnittränder der Säcke umzunähen und die Säcke an die Seile zu binden. Es werden einfachere Anbringungstechniken benötigt.

Witterungsbeständigkeit

Die Aufstellung des Prototyps im Freien hat gutes Witterungsverhalten gezeigt, sogar während einer starken Regenzeit. Nach drei Monaten ist die Oberfläche noch in zufriedenstellendem Zustand; es ging nur etwas leicht-gebundener Sand verloren, aber Lecks entwickelten sich nicht.

Appearance

Although the cement impregnated sack finish was quite rough, and much more work is needed to improve fabrication techniques, the overall appearance of the roof was fairly pleasing. Its similarity to the appearance of clay tile could improve its chances of acceptance, especially if a pigment could be incorporated into the mix to provide reddish-brown color.

Installation

Considerable difficulty was encountered due to excessive sagging of the sacks between the rope supports, and it appears that some other support system should be developed. Also, sewing the cut edges of the sacks and tying them to the ropes was a laborious and time-consuming procedure. Simpler installation techniques are needed.

Resistance to Exposure

The prototype stood up well in exposure tests even during a period of very heavy rainfall. After three months, the sample is still in satisfactory condition; only some lightly-bonded superficial sand was lost, and leaks did not develop.

Rahmen für die Erprobung verschiedener Unterkonstruktionen und Bedachungsmaterialien

Framework for testing different substructures and roofing materials

Abb. 6.6 Unterkonstruktion: Hühnermaschendraht
Fig. 6.6 Substructure: chicken-wire mesh

Abb. 6.7 Unterkonstruktion: Bambus und Seil
Fig. 6.7 Substructure: bamboo and rope

Abb. 6.8 Unterkonstruktion: caña de castilla
Fig. 6.8 Substructure: caña de castilla

Gewicht

Das Gewicht der Dachdeckung betrug durchschnittlich ca. 14,3 kg/m^2, was, wenn auch schwerer als verzinkter Stahl, viel geringer ist als das Gewicht eines Tonziegeldaches (62 kg/m^2).

Schlußfolgerungen

Das Konzept, zementimprägnierte Säcke als Dachdeckung zu verwenden, indem sie über ein Tragsystem gelegt werden, das einen Welleffekt wie bei Tondachziegeln erzeugt, sollte unbedingt weiterverfolgt werden. Es muß jedoch viel Arbeit erbracht werden, um bessere Herstellungstechniken und Tragsysteme zu entwickeln, ehe dieses Dachdeckungssystem als zufriedenstellend angesehen werden kann.

Weight

The weight of the roof covering averaged about 14.3 kg/m^2, which, although heavier than galvanized steel, is far less than the weight of a clay tile roof (62 kg/m^2).

Conclusions

The concept of using cement impregnated sacks as a roof covering laid over a support system designed to provide an overall corrugated effect similar to the appearance of clay tile, definitely should be pursued further. However, much work is needed in developing better fabrication techniques and in support system design before this roofing system can be considered satisfactory.

1-2 Zement-Sand oder stabilisierte Erde auf Rohrunterkonstruktion

Die nächste Quadratmeter-Fläche wurde mit Rohrstangen (caña de Castilla) ausgelegt, die geschnitten und in vertikaler Richtung nebeneinandergelegt wurden. Diese wurden an drei in gleichen Abständen horizontal verlaufenden Rohren angebunden, die selbst am äußeren Rahmen befestigt wurden. Von links

1-2 Cement-sand or Stabilized Soil Applied Over Cane Support

The next square meter space was filled with canes (caña de Castilla) cut to length and laid one next to the other in a vertical direction. These were tied in place to three equidistant canes running in a horizontal direction and attached to the exposure deck frame. One vertical half of the area was covered

beginnend, wurde die halbe Fläche mit einer Mischung aus einem Teil Zement und zwei Teilen Bims bedeckt, und die andere Hälfte mit stabilisierter Erde (10% Löschkalk).
Auf dem Teil mit stabilisierter Erde wurde die Hälfte mit Erde unter Hinzufügung von imprägnierenden Zusätzen (siehe Abschnitt 6.1) bedeckt, die andere Hälfte mit unbehandelter Erde. Die Ergebnisse waren wie folgt:

Äußeres Erscheinungsbild
Die Dachdeckung, entweder aus Zement oder Erde, sieht nicht wie Tonziegeldachdeckung aus und ist nicht besonders attraktiv. Die drei Rohrverbindungselemente wurden in horizontaler Richtung angebracht, um ein Abgleiten der Mischung beim Auftragen zu verhindern; in der Praxis wurde dies jedoch für unnötig befunden. Offensichtlich sollten diese Stützen vertikal verlaufen, um eine attraktivere Wellwirkung zu erzielen.

Aufbau
Die für dieses Experiment benützten Rohre sind nicht so gerade wie Bambus, so daß die Verlegung der krummen Stäbe und deren Anbindung an die horizontalen Teile problematisch war. Es wurde ein 2-Mann-Team zum Aufbau benötigt. Das Auftragen der Mischung über die Rohre war keine schwierige Angelegenheit.

Witterungsbeständigkeit
Die Zement-Bims-Mischung zeigte gute Widerstandsfähigkeit gegen Wettereinflüsse. Die Probe aus stabilisierter Erde ohne wasserdichtende Zusätze zeigte fast unmittelbar nach dem Regen schwere Auswaschungen. Die wasserdichte Erdschicht war dem unbehandelten Muster weit überlegen, zeigte jedoch auch noch einen Grad von Erosion, der nicht akzeptiert werden konnte.

Gewicht
Das geschätzte Gewicht von 20,1 kg/m^2 für Zement-Bims und 22,7 kg/m^2 für stabilisierte Erde ist schwerer als dasjenige der zement-imprägnierten Säcke aus dem vorhergehenden Experiment. Diese Gewichtszahlen betragen jedoch nur ein Drittel des Gewichtes von Tondachziegeln.

Schlußfolgerungen

a) Eine Zement-Bims-Mischung, auf einer Rohrkonstruktion aufgetragen, scheint weitere Experimente zu rechtfertigen, besonders wenn man in Betracht zieht, daß dieses Material durch die Anwendung von Fasermaterialien noch verstärkt werden kann.

b) Stabilisierte Erde kann offensichtlich für diese Art der Anwendung nicht in Betracht gezogen werden, wenn kein Oberflächenschutz gegen Erosion vorgesehen wird.

c) Die bei diesem Experiment verwendete Unterkonstruktion sollte vollkommen neu gestaltet werden, um ein attraktiveres Erscheinungsbild des Daches zu erreichen.

with a mixture of one part cement to two parts pumice, and the other half with stabilized soil (10% hydrated lime).
In the stabilized soil section, half of the area was covered with soil containing waterproofing additives (see Section 6.1), and the other half with untreated soil. The results of this experiment were as follows:

Appearance
The roof covering, using either cement or soil, does not simulate the appearance of clay tile, and is not particularly attractive. The three cane support members were installed in a horizontal direction to prevent slippage of the mixture when trowelling, however, in practice this was found to be unnecessary. Obviously, these supports should run vertically in order to provide a more attractive corrugated effect.

Installation
The canes used for this experiment are not as straight as bamboo, and cane curvature was a problem in laying the supports and tying them to the horizontal members. A two-man installation team was required. Trowelling the mixture over the canes was not a difficult operation.

Resistance to Exposure
The cement-pumice mixture showed good resistance to exposure. The stabilized soil sample without waterproofing additives showed almost immediate severe erosion when exposed to rainfall. The waterproofed soil was far superior to the untreated sample, but still exhibited an unacceptable degree of erosion.

Weight
The estimated weight of 20.1 kg/m^2 for cement-pumice, and 22.7 kg/m^2 for the stabilized soil is heavier than that of the cement-impregnated sacks described in the previous experiment. These weights, however, are only about a third of the weight of clay tile.

Conclusions

a) A cement-pumice mixture applied over a cane support appears to merit further experimentation, especially when considering that this material can be further strengthened through the use of fibrous reinforcing materials.

b) Stabilized soil apparently cannot be considered for this type of application unless surface protection against erosion is provided.

c) The support system used in this experiment should be completely redesigned to provide a more attractive roof appearance.

1-3 Stabilisierte Erde mit Oberflächenbehandlung über Rohrunterkonstruktion

Der letzte Freiraum des Befestigungsrahmens wurde ähnlich wie bei dem vorhergehenden mit Rohr gefüllt, jedoch mit dem Unterschied, daß die Rohrstäbe in horizontaler Richtung übereinandergelegt und an drei vertikalen, in gleichem Abstand befestigten Stützelementen angebunden wurden. Das Rohrtragesystem wurde mit 10% kalkstabilisierter Erde bedeckt und in drei vertikale Abschnitte eingeteilt, wobei jeder eine andere Oberflächenbehandlung erhielt. Auf den ersten Abschnitt wurde Kalkschlämme aufgestrichen, nachdem die Erde einige Tage lang trocknen konnte. Beim zweiten Abschnitt wurde Baumwollgewebe zugeschnitten, in Kalkschlämme getaucht und auf die vorg .richene Fläche gelegt. Das imprägnierte Baumwollgewebe erhielt einen zusätzlichen Kalkanstrich, um den Stoff zu glätten.

Auf die Hälfte der restlichen Fläche wurde Stroh (pajón) in die nasse stabilisierte Erde gedrückt, um seine Wirksamkeit als Oberflächenschutz zu erproben. Ein Teil des Strohs wurde zum zusätzlichen Schutz mit Bitumen überstrichen; der Rest blieb unbehandelt. Die andere Hälfte dieser Fläche wurde mit zugeschnittenen Sackstreifen, die mit stabilisierter Erde imprägniert waren, bedeckt, die ihrerseits mit Stroh bedeckt wurden, während sie noch naß waren. Die Sackstreifen überlappten jeweils die darunterliegenden Strohschichten, um sie vor allem nach der Trocknung festzuhalten.

Die folgenden Ergebnisse wurden erzielt:

Äußeres Erscheinungsbild

Die Gesamterscheinung dieses Dachdeckungssystems wurde gegenüber dem vorangegangenen Experiment verbessert, ähnelt jedoch noch nicht ganz dem Tonziegeldach. Der Abstand zwischen den drei vertikalen Stäben war zu groß und die Stäbe selbst hatten zu geringen Durchmesser, um die gewünschte Kontur zu erreichen. Dieses Problem müßte jedoch durch die Neugestaltung der Unterkonstruktion korrigiert werden können.
Der zum Oberflächenschutz benützten Kalkschlämme sollten Pigmente beigegeben werden, um eine Tondachziegel-ähnliche Farbe zu erhalten.
Die Erscheinung der strohdegeckten stabilisierten Erde ist schlecht. Es war schwer, eine gute Haftung des Strohs mit der Erde zu erreichen, und die Abdeckung war nicht gleichmäßig.

Aufbau

Hier treffen dieselben Bemerkungen zu wie beim vorhergehenden Experiment.

Witterungsbeständigkeit

Obwohl fast sofort zahlreiche feine Risse in der Kalkoberflächenschicht entstanden, haben diese sich nicht weiter ausgebreitet, und die Probe blieb intakt, ohne nach zweimonatiger Wettereinwirkung Anzeichen von Erosion zu zeigen. Die Rissebildung war höchstwahrscheinlich auf eine zu dicke Kalkschlämme zurückzuführen.
Zwischen dem Oberflächenschutz mit Baumwollgewebe und -bewehrung und

1-3 Stabilized Soil With Surface Protection Over Cane Support

The last exposure deck section was filled with canes in a similar manner to the last experiment, except that the canes were laid one next to the other in a horizontal direction and tied to three equidistant vertical support members. The cane support system was covered with 10 percent lime-stabilized soil, and was divided into three vertical sections, each with a different type of surface protection.
The first section was brush-coated with a heavy lime slurry, after the soil had dried for several days. In the second area, cotton fabric was cut to size, immersed in a lime slurry, and placed directly over the stabilized soil. A second coat of lime was brushed over the impregnated cotton fabric.

On half of the remaining area, straw (pajón) was pressed into the wet stabilized soil to evaluate its effectiveness as surface protection. Part of the straw was coated with bitumen for added protection; the rest was untrected. The other half of this area was covered with stabilized soil impregnated sacks which, in turn, were covered with straw while still wet.

The following results were obtained:

Appearance

The overall appearance of this roofing system was improved over the last experiment, but still does not closely resemble the appearance of clay tile. The spacing between the three vertical supports was too great, and the supports themselves of too small a diameter to provide the desired contour. This problem, however, should be correctable through redesign of the support system.
The lime slurry used for surface protection probably should be pigmented to provide a clay tile-like coloring.
The appearance of the straw-covered stabilized soil is poor. Difficulty was encountered in obtaining good adhesion of the straw to the soil, and covering was not uniform.

Installation

Same comments as the last experiment.

Resistance to Exposure

Although numerous fine cracks (crazing) appeared almost immediately in the lime surface coating, these have not propagated further, and the specimen remains intact without signs of erosion after two months exposure. The crazing was most likely due to the use of too heavy a lime slurry concentration.
No significant difference was noted between the cotton fabric reinforced surface protection and the area with lime slurry alone.

der Fläche nur mit Kalk konnte kein nennenswerter Unterschied festgestellt werden.
Die strohbedeckte Probe war besser als man erwartet hatte, aber die durch Strohausfall freigelegten Erd-Kalk-Flächen beginnen nach zwei Monaten zu zerfallen.

Gewicht
Das geschätzte Gewicht der Dachdeckung ist dasselbe wie beim letzten Experiment, ca. 23 kg/m^2.

Schlußfolgerungen

a) Es wird als der Mühe wert angesehen, weitere Experimente mit stabilisierter Erde, mit Kalkanstrich geschützt (mit oder ohne Baumwollgewebe-Verstärkung), durchzuführen als möglicher preisgünstiger Ersatz für das Zement-Bims-Dach. Es sind jedoch viel mehr grundlegende Untersuchungen in bezug auf Erdauswahl, Optimierung der Kalkkonzentrationen und der Unterkonstruktions-Gestaltung, erforderlich.

b) Für die Anwendung von Stroh als Oberflächenschutz für stabilisierte Erde werden weitere Arbeiten nicht empfohlen.

The straw-covered sample stood up better than expected, but areas with exposed soil are beginning to deteriorate after two months exposure.

Weight
The estimated roof covering weight is the same as the last experiment, about 23 kg/m^2.

Conclusions

a) Further experimentation with stabilized soil protected with lime slurry (with or without cotton fabric reinforcement) is considered worthwhile as a possible lower cost substitute to the cement-pumice roof. Much more basic testing is necessary, however, relative to soil selection, optimization of lime slurry concentrations and support system design.

b) No further work is recommended with the use of straw as a surface protection for stabilized soil.

Fig. 6.24 Sections of the pajón covering received a coat of Conservex for waterproofing.

Zweite Versuchsreihe

Für die zweite Versuchsreihe über Dachdeckungssysteme wurden 50 x 50 cm große Probeplatten, bestehend aus einem Rohrgerüstbau und Dachdeckung, hergestellt und später, auf einem weiteren geneigten Rahmen befestigt, im Freien aufgestellt. Es wurden insgesamt sieben Muster angefertigt, einschließlich einem mit Unterkonstruktion aus gespaltenem und flachgedrücktem Rohr, das mit einer Schnur zusammengebunden und mit stabilisierter Erde bedeckt wurde. In der Praxis stellte sich heraus, daß es zu schwierig war, das zerdrückte Rohr zu verarbeiten und handhaben, deshalb wurde diese Idee aufgegeben.

Die anderen sechs Muster werden nachstehend beschrieben:

2-1 Zement-imprägnierte Säcke

Es wurden drei Muster hergestellt mit einem Rohrgerüst, bestehend aus Stäben, die in gleichen Abständen in Fallrichtung verliefen und mit Schnur an zwei darunterliegenden horizontal verlaufenden, vorgekerbten Stäben angebunden waren. Der Abstand zwischen den vertikalen Rohren wurde von Muster zu Muster verändert (5; 7,5 und 10 cm), um die Wirkung auf das Erscheinungsbild des Daches zu erproben und um Unterschiede in Einheitsgewicht und Festigkeiten festzustellen.

Sisal- und Jutesäcke wurden in 35 x 65 cm große rechteckige Teile geschnitten und in eine nasse Mischung aus einem Teil Zement und zwei Teilen Bims getaucht. Über jedes Rohrgerüst wurden zwei Säcke gelegt, die sich um etwa 20 cm überlappten und zwischen den vertikalen Stäben einsinken konnten, was dem Dach ein wellenförmiges Aussehen verlieh. Mit einer Bürste wurde ein Endanstrich aus Zement-Bims auf jedes Muster aufgetragen.
Die Ergebnisse waren folgende:

Abb. 6.25 Vorbereitung einer Unterkonstruktion aus caña de castilla: Kerben werden in gleichen Abständen geschnitzt, in denen Querstäbe einrasten.

Fig. 6.25 Preparation of sample substructure using caña de castilla: notches are cut at equal intervals to keep cross members in place.

Second Series

For the second series of roofing system experiments, 50 x 50 cm prototypes, including cane support system and roof covering, were fabricated and later attached to another exposure deck. A total of seven specimens were prepared, including one with a support system consisting of split and crushed cane tied together with twine, and covered with stabilized soil. In practice, the crushed cane was found too difficult to process and handle, and this idea was discarded.

The other six specimens are described below:

2-1 Cement-impregnated Sacks

Three specimens were prepared with support structures consisting of canes laid parallel in a vertical direction and tied with twine to two horizontal canes running underneath the vertical members. The spacing between the vertical canes was varied from sample to sample to evaluate the effect upon the roof appearance (5, 7.5 and 10 cm).

Sisal and jute sacks were cut into 35 x 65 cm rectangular sections and were immersed in a wet mixture of one part cement to two parts pumice. Two sacks were placed over each prototype support system, with an overlap of about 20 cm, and were allowed to sag between the parallel vertical supports, thereby providing a corrugated appearance to the roof. A final cement-pumice coating was brushed onto each specimen with a brush.
Results were as follows:

Äußeres Erscheinungsbild

Der Welleneffekt war, obwohl etwas unregelmäßig, bei allen Mustern recht gefällig. In bezug auf Wellenfrequenz waren alle Elemente akzeptabel, wobei die 7,5 cm-Abstände das gängige Wellblechmaß ist. Die äußere Erscheinung entsprach insgesamt den Asbestzement- und Zinkblech-Wellplatten, nicht so sehr den Tondachziegeln, aber die Anwendung dieser Methode bei großflächigeren Konstruktionen mit schwererem Bambus- oder Rohrgerüst könnte ein besseres Aussehen der Dachfläche bewirken.

Aufbau

Der Aufbau dieses Systems war beträchtlich einfacher als derjenigen der ersten Probeserien. Die meisten Schwierigkeiten lagen darin, ein einheitliches Einsinken der imprägnierten Säcke zwischen den vertikalen Stützenelementen zu erreichen. Um diesen Vorgang zu erleichtern, sollte in Zukunft eine Art Schablone vorgesehen werden.

Appearance

The corrugated effect, although lacking uniformity, was fairly pleasing on all samples, with little difference noted between the support spacing variations. On these samples, the effect more closely approximates the appearance of asbestos-cement or galvanized steel than clay tile, however, the application of this concept to larger scale constructions, with heavier bamboo or cane supports, could result in a better contoured roof surface.

Installation

The construction of this system was considerably simpler than those used in the first series of experiments. Most difficulty was encountered in attempting to obtain uniform sagging of the impregnated sacks between the vertical support members; a fixture should be designed in the future to facilitate this operation.

Abb. 6.26 Caña-Rahmen, fertig für den Überzug: Sisalsack wird in Bims-Zement-Mischung getaucht.

Fig. 6.26 Caña framework ready to receive covering: sisal sack dipped in cement-pumice mix.

Abb. 6.27 Erste Schicht der Dachdeckung wird auf die Rahmenkonstruktion gelegt und sanft in die Zwischenräume gedrückt, um Wellen zu bilden und besseren Halt zu gewährleisten.

Fig. 6.27 First layer of roof covering laid on framework and gently pressed into gaps to simulate corrugation and give better hold on substructure.

Witterungsbeständigkeit
Die mit Zement-Bims imprägnierten Säcke wurden zwei Monate lang der Witterung ausgesetzt; die Witterungsbeständigkeit war zufriedenstellend.

Gewicht
Das Durchschnittsgewicht der imprägnierten Sack-Dachdeckung war ungefähr 20 kg/m^2.

Schlußfolgerungen
Die Dachdeckung mit Zement-Bims-imprägnierten Säcken erscheint weiterhin vielversprechend, obwohl noch mehr unternommen werden sollte, um die Herstellungstechniken zu verbessern. Außerdem sind weitere Tests erforderlich, um die Haltbarkeit über längere Zeiträume festzustellen.
Die Unterkonstruktion, die aus parallelen vertikalen Rohrstäben oder Bambuspfosten besteht, die an die darunter verlaufenden horizontalen Elemente gebunden werden, ist eine Verbesserung gegenüber den Systemen aus der ersten Experimentenreihe. Die Optimierung dieses Systems sollte eines der primären Ziele jeglichen zukünftigen Experimentierprogramms sein.

Resistance to Exposure
Resistance of the cement-pumice impregnated sacks to the elements has been satisfactory over a two months exposure period.

Weight
The average weight of the impregnated sack roof covering was approximately 20 kg/m^2.

Conclusions
The cement-pumice impregnated sack roof covering continues to appear promising although more effort is needed to improve fabrication techniques, and more testing is required to prove resistance over longer periods of time.
The support system consisting of parallel vertical canes or bamboo poles tied to horizontal members running underneath, is an improvement over the systems evaluated in the first series of experiments. Optimization of the design of this system should be one of the prime goals of any future experimental program.

Fig. 6.29 Tying the sacking material to the framework.

2-2 Mit stabilisierter Erde imprägnierte Säcke

Es wurde ein Muster ähnlich denjenigen in Experiment 2-1 hergestellt (7,5 cm Abstand zwischen vertikalen Stäben), außer daß die Säcke mit einer Erd-Kalk-Mischung (10% Löschkalk) imprägniert wurden, statt mit einer Zement-Bims-Mischung. Nach der Trocknung wurde eine Hälfte der Probe mit Kalkschlämme bestrichen, die andere Hälfte blieb unbehandelt.

Es wurden folgende Ergebnisse erzielt:

Äußeres Erscheinungsbild
Abgesehen vom Farbunterschied war die Gesamterscheinung des Musters ähnlich wie Experiment 2-1.

Aufbau
Siehe Bemerkungen bei 2-1.

Witterungsbeständigkeit
Sowohl die ungeschützte Fläche als auch die mit Kalkschlämme behandelte zeigte eine Anzahl von Rissen zu Beginn des Tests. Später wurde auf der unge-

2-2 Stabilized Soil Impregnated Sacks

A sample was prepared in an identical manner as those described in experiment 2-1 (7.5 cm spacing between vertical supports), except that the sacks were impregnated with soil stabilized with 10 percent hydrated lime, instead of cement-pumice. After drying, one half of the specimen was covered with lime slurry; the other half was left unprotected.

The following results were obtained:

Appearance
Except for the color difference, the overall appearance of the specimen was similar to experiment 2-1.

Installation
Same comments as 2-1.

Resistance to Exposure
Both the unprotected area and the section coated with lime slurry showed a number of cracks early in the exposure test, and flaking and erosion was ob-

Abb. 6.30 Ähnliches Dachelement mit Erd-Kalk-Mischung statt Bims-Zement-Mischung.

Fig. 6.30 Similar roofing element using soil-lime mix, instead of cement-pumice.

Abb. 6.31 Ähnliches Dachelement wie Abb. 6.26, aber Überbrückung der Lücke mit Pajón, um zu verhindern, daß die Bims-Zement-Mischung hindurchfällt.

Fig. 6.31 Similar roofing element as in Fig. 6.26, but gaps filled with pajón to prevent cement-pumice covering from falling through.

schützten Fläche Abblättern und Erosion festgestellt. Im allgemeinen kann die Witterungsbeständigkeit als nicht zufriedenstellend angesehen werden.

Gewicht
Das Durchschnittsgewicht der Dachdeckung wurde auf 15 kg/m^2 geschätzt.

Schlußfolgerungen
Wie bei den Witterungstests gezeigt, unterliegen die mit Erde imprägnierten Säcke physikalisch denjenigen mit Zement-Bims, und weitere Arbeit an diesem Dachdeckungssystem sollte als nicht vorrangig angesehen werden.

2-3 Unbewehrter Zement-Bims über Rohrgerüst

Es wurde ein Muster hergestellt mit einem Rohrgerüst wie bei den letzten Experimenten beschrieben, und mit einer Mischung aus einem Teil Zement und zwei Teilen Bims bedeckt. Eine dünne Lage Stroh diente als Füllmaterial zwischen den vertikalen Stäben, um die Zementschicht bis zur Trocknung abzustützen.

Aus diesem Experiment liegen folgende Ergebnisse vor:

served in the unprotected section. In general, resistance to exposure can be considered unsatisfactory.

Weight
The average weight of the roof covering was estimated at 15 kg/m^2.

Conclusions
As shown by the exposure tests, the soil impregnated sacks are physically inferior to those with cement-pumice, and any further work done with this type of roof covering system should be considered of low priority.

2-3 Cement-pumice Over Cane Support

A specimen was prepared with a cane support system identical to those described in the last experiments, and was then covered with a mixture of one part cement to two parts pumice. A thin layer of straw was used as a filler between the vertical supports to prevent spillage of the cement mixture.

Results of this experiment were as follows:

Abb. 6.32 Bims-Zement-Mischung ohne Sackmaterialverstärkung.

Fig. 6.32 Cement-pumice covering without sacking material reinforcement.

Abb. 6.33 Fertiges Dachelement mit glatter Oberfläche und Wellplattenform.

Fig. 6.33 Finished roofing element with smoothened surface and corrugated appearance.

Äußeres Erscheinungsbild
Die Gesamterscheinung dieses Musters war nicht so gut wie das vorhergehende mit den imprägnierten Säcken, da der Welleneffekt viel weniger deutlich wurde. Der Grund dafür waren die Schwierigkeiten beim Auftragen der Mischung über dem Rohrgerüst mit einer Kelle; um diesen Vorgang besser kontrollieren zu können, wird eine Form benötigt.

Aufbau
Die Herstellung dieser Art von Dachdeckung ist nicht besonders schwierig. Es ist jedoch, wie bereits oben erwähnt, erforderlich, einige Werkzeuge und Formen zu entwickeln, um die Fertigungstechnik zu verbessern und einheitliche, klar erkennbare Wellenformen anzubringen.

Witterungsbeständigkeit
Kurz nach Herstellung der Probe zeigte sich ein vertikaler Riß parallel zu einer der Wellen. Dies kann zum Teil auf Schrumpfung zurückzuführen sein, die Hauptursache war jedoch die fehlende gleichmäßige Dicke des Materials aufgrund schlechter Auftragtechnik. Nach zwei Monaten im Freien wurden keine weiteren Auswirkungen beobachtet.

Gewicht
Das Durchschnittsgewicht der Zement-Bims-Abdeckung war ca. 20 kg/m^2.

Schlußfolgerungen
Da diese Methode eine Kostenreduzierung durch das Weglassen von gekauften Säcken bewirken kann, sollten weitere Experimente durchgeführt werden. Die Entwicklung von einfachen Geräten zur Verbesserung der Herstellungstechniken, Evaluierung der Anwendung von Naturfasern als Verstärkung und Optimierung der Unterkonstruktion sollten die wichtigsten Aufgaben sein, die bei einem weiteren Experimentierprogramm durchgeführt werden sollten.

2-4 Unbewehrte stabilisierte Erde auf Rohrgerüst

Dieses Probestück wurde in gleicher Weise wie im Experiment 2-3 hergestellt, außer daß 10% kalkstabilisierte Erde statt der Zement-Bims-Mischung als Dachdeckung verwendet wurde. Nach der Trocknung wurde die Hälfte der Fläche nur mit Kalkschlämme bestrichen; die andere Hälfte wurde zusätzlich mit kalkimprägniertem Baumwollmaterial bedeckt und nochmals mit Kalkanstrich versehen.

Es wurden folgende Ergebnisse erzielt:

Äußeres Erscheinungsbild
Es entstanden dieselben Schwierigkeiten mit schlecht ausgebildeten Wellen wie bei Experiment 2-3.

Aufbau
Siehe 2-3.

Appearance
The overall appearance of this sample was not as good as the previous impregnated sack experiment, since the corrugated effect was far less pronounced. This was due to difficulties encountered in contouring the mixture over the supports with a trowel, and a form is needed to permit better control over this operation.

Installation
The fabrication of this type of roofing system is not a particularly difficult operation. However, as mentioned above, some equipment development work is needed to improve trowelling technique and provide uniform well-defined corrugations.

Resistance to Exposure
Shortly after preparation of the sample, a vertical crack appeared running parallel to one of the corrugations. This may have been partially due to shrinkage but the primary cause was lack of material thickness uniformity due to poor trowelling technique. After two months exposure, no other defects have been observed.

Weight
The average weight of the cement-pumice covering was about 20 kg/m^2.

Conclusions
Since this method can result in cost reduction through the elimination of the purchased sacks, more experimentation should be carried out. Development of simple equipment to facilitate fabrication, evaluation of the use of natural fibres as reinforcement and optimization of the support system design should be the principal tasks included in any new experimental program.

2-4 Stabilized Soil Over Cane Support

This sample was prepared in an identical manner to experiment 2-3, except that 10% lime-stabilized soil was used as the covering instead of the cement-pumice mixture. After drying, half of the specimen was coated with a lime slurry; the other half was covered with lime impregnated cotton fabric and given a final brushed-on coating of lime slurry.

The following results were obtained:

Appearance
The same difficulties with poorly defined corrugations were encountered as with experiment 2-3.

Installation
Same comments as 2-3.

Abb. 6.34 Dachelemente mit Unterkonstruktion aus caña und mit Bims-Zement-Mischung getränkter Sackmaterialdeckung. Einzige Unterschiede liegen im Abstand der cañas: 5 cm, 7,5 cm, und 10 cm.

Fig. 6.34 Roofing elements with caña substructure and cement-pumice impregnated covering, only differing in caña spacing: 5 cm, 7,5 cm and 10 cm.

Abb. 6.35 Dachelemente zur Erprobung im Freien, auf geneigtem Rahmen befestigt. Die Bims-Zementtafeln erhielten keine Oberflächenbehandlung, aber die Erd-Kalkproben wurden mit unterschiedlichen Schutzschichten versehen: Kalkanstrich mit oder ohne Stoffverstärkung und Conservex. Zum Vergleich wurde ein Teil der Oberfläche nicht behandelt.

Fig. 6.35 Roofing elements placed on framework for exposure testing. The cement-pumice samples received no surface treatment, but the soil-lime specimens received different protective coatings: limewash, with and without cloth reinforcement and Conservex. For comparison a section was left unprotected.

Abb. 6.36 Aufstellung aller Bedachungselemente im Freien, um die Auswirkungen von Sonnenstrahlung, Wind, Regen, Temperatur- und Feuchtigkeitsschwankungen sowie möglicherweise von Erdstößen zu untersuchen.

Fig. 6.36 Exposure of all roofing specimens, to test the effects of solar radiation, wind, rain, fluctuations in temperature and humidity and possibly earth tremors.

Witterungsbeständigkeit

Außer der oberflächlichen Rissebildung der Kalkschicht überstand die mit Baumwollmaterial geschützte Fläche die zweimonatige Probezeit gut. Die nur mit Kalk geschützte Fläche war sehr aufgerissen, zum Teil aufgrund von Beschädigungen bei der Handhabung, als das Probestück auf dem geneigten Rahmen befestigt wurde.

Gewicht

Das Durchschnittsgewicht für die Dachdeckung aus stabilisierter Erde mit Kalkanstrich wird auf ca. 26 kg/m^2 geschätzt.

Schlußfolgerungen

Wie bei den Schlußbemerkungen des Experiments 1-3, ist noch viel Basisforschung bei der Evaluierung der Erdauswahlmethoden sowie bei den Stabilisierungs- und Kalkanstrich-Techniken erforderlich, ehe entschieden werden kann, ob dieses Material in weiteren Prototyp-Experimenten getestet werden sollte oder nicht.

Resistance to Exposure

Except for superficial glazing of the lime coating, the area protected by cotton fabric stood up well to two months of exposure. The area protected with lime alone was badly cracked, partially due to damage during handling when attaching the specimen to the exposure deck.

Weight

Average weight for the stabilized soil covering with a lime coating is estimated to be about 26 kg/m^2.

Conclusions

As mentioned in the comments covering experiment 1-3, much more basic experimentation is necessary to evaluate soil selection methods, stabilization and lime coating techniques before a decision can be made as to whether this material should be tested further in prototype experiments or not.

6.2.2.2 Vorläufige Kostenschätzungen

Wie bereits früher in diesem Bericht erwähnt, ist das Dachdeckungssystem aus verzinktem Stahlblech die preiswerteste Alternative zum traditionellen Strohdach, die dem Hausbesitzer mit niedrigem Einkommen in Zentralamerika zugänglich ist. Die durchschnittlichen Gesamtbaukosten für dieses System sind, nach Schätzungen örtlicher Institutionen, 14 $/m^2, und werden folgendermaßen aufgeschlüsselt:

Position	Kosten/m^2
Galvanisierter Stahl (1)	4,75
Holz für Unterkonstruktion	1,90
Lohn	2,85
Abgehängte Decke (Holzplanken)	4,50
Insgesamt	14,00

Wird die abgehängte Decke weggelassen, so verringern sich die Gesamtkosten auf 9,50$/m^2.

Da angenommen werden kann, daß der Lohn für einen Hausbesitzer auf dem Lande, der sein eigenes Dach baut, kein wichtiger Faktor ist, dürften sein Hauptproblem, vom wirtschaftlichen Standpunkt aus betrachtet, wahrscheinlich die direkten Materialkosten für die Dachdeckung und Unterkonstruktion sein, welche in diesem Fall 6,65 $/m^2 betragen.

(1) einschl. Überlappung, Verschnitt, Nägel und Zusatzmaterial für die Firstabdeckung

6.2.2.2 Preliminary Cost Considerations

As mentioned previously in this report, the lowest cost alternative to the traditional thatched roof, available to the low-income home owner in Central America, is the galvanized steel roofing system. The average total construction cost for this system, as estimated by local institutions, is $ 14/m^2, and includes the following items:

Item	Cost/m^2
Galvanized steel (1)	4.75
Lumber for support system	1.90
Labour	2.85
False ceiling (wooden planks)	4.50
Total	14.00

If the false ceiling is eliminated, the total cost drops to $ 9.50/m^2.

Since labor may not be an important factor for the rural home owner who builds his own roof, his major concern from an economic standpoint probably would be the direct material cost for the roof covering and supports which, in this case, amounts to $ 6.65/m^2.

(1) Includes overlap, scrap, nails and the extra material required to cover the ridge.

Um dem Verbraucher einen wirtschaftlichen Vorteil zu bieten, sollte daher jedes neu einzuführende Dachdeckungssystem (Abdeckung und Unterkonstruktion) einen Materialkaufpreis haben, der bedeutend unter den oben erwähnten entsprechenden Kosten für das Dach aus verzinktem Stahlblech liegt.

In den nachstehenden Tabellen werden Schätzpreise der Materialkosten pro m^2 aufgeführt für jedes der im letzten Abschnitt beschriebenen Prototyp-Experimente, unter der Voraussetzung, daß Materialien wie Bambus, Rohr, Erde, Sand und Bims kostenlos im Felde gesammelt werden können. Wie man sehen kann, variieren die Kosten von mindestens 0,23 $/$m^2$ bis zu maximal 3,58 $/$m^2$, alle beträchtlich niedriger als die Kosten für galvanisiertes Stahlblech.

In order to represent an economic advantage to the consumer, therefore, any new roofing system to be introduced (covering and support) should represent a purchased material cost significantly less than the equivalent cost shown above for the galvanized steel roof.

In the following tables, estimates have been prepared of the material cost per square meter for each of the prototype experiments discussed in the last section, assuming that materials such as bamboo, cane, soil, sand and pumice can be gathered in the field without cost. As can be seen, costs vary from a minimum of $ 0.23/m^2 to a maximum of $ 3.58/m^2, all considerably lower than galvanized steel costs.

Geschätzte Materialkosten

Experiment 1-1

Dachdeckung: Sisalsäcke mit Zement-Sand-Mischung imprägniert.
Unterkonstruktion: Bambus und Seil.

Material	Einheit	Menge pro m^2	Einheitspreis ($)	Preis pro m^2 ($)
Bambus	m	3,20	-	-
Seil	m	10,80	0,08	0,86
Sisal-Säcke	m^2	1,90	1,09	2,07
Bindfaden	m	10,00	0,01	0,10
Zement	kg	6,90	0,08	0,55
Sand	kg	13,50	-	-
Gesamtkosten/m^2				3,58

Experiment 1-2 (a)

Dachdeckung: Zement-Bims-Mischung.
Unterkonstruktion: an Horizontalstäbe mit Bindfaden gebundene, dicht angeordnete Rohrstruktur.

Material	Einheit	Menge pro m^2	Einheitspreis ($)	Preis pro m^2 ($)
Rohr	m	42,00	-	-
Bindfaden	m	10,00	0,01	0,10
Zement	kg	10,70	0,08	0,86
Bimssand	kg	9,40	-	-
Gesamtkosten/m^2				0,96

Material Cost Estimate

Experiment 1-1

Covering: Sisal sacks impregnated with cement-sand mixture.
Support: Bamboo and rope.

Material	Unit	Quantity per m^2	Unit cost ($)	Cost per m^2 ($)
Bamboo	m	3.20	-	-
Rope	m	10.80	0.08	0.86
Sisal sacks	m^2	1.90	1.09	2.07
Twine for tying sacks	m	10.00	0.01	0.10
Cement	kg	6.90	0.08	0.55
Sand	kg	13.50	-	-
Total cost/m^2				3.58

Experiment 1-2 (a)

Covering: Cement-pumice mixture.
Support: Solid cane structure tied with twine to horizontal cane supports.

Material	Unit	Quantity per m^2	Unit cost ($)	Cost per m^2 ($)
Canes for support	m	42.00	-	-
Twine	m	10.00	0.01	0.10
Cement	kg	10.70	0.08	0.86
Pumice	kg	9.40	-	-
Total cost/m^2				0.96

Experiment 1-2 (b)

Dachdeckung: 10% Kalk-stabilisierte Erde ohne Oberflächenschutz.
Unterkonstruktion: an Horizontalstäbe mit Bindfaden gebundene, dicht angeordnete Rohrstruktur.

Material	Einheit	Menge pro m^2	Einheits-preis (Sh)	Preis pro m^2 (Sh)
Rohr	m	42,00	-	-
Bindfaden	m	10,00	0,01	0,10
Erde	kg	21,70	-	-
Löschkalk	kg	1,80	0,07	0,13
Gesamtkosten/m^2				0,23

Experiment 1-3

Dachdeckung: 10% Kalk-stabilisierte Erde mit Kalkanstrich.
Unterkonstruktion: an Vertikalstäbe mit Bindfaden gebundene, dicht angeordnete Rohrstruktur.

Material	Einheit	Menge pro m^2	Einheits-preis (Sh)	Preis pro m^2 (Sh)
Rohr	m	42,00	-	-
Bindfaden	m	10,00	0,01	0,10
Erde	kg	20,50	-	-
Löschkalk				
- als Bindemittel	kg	1,80	0,07	0,13
- als Anstrich	kg	1,90	0,07	0,13
Gesamtkosten/m^2				0,36

Experiment 2-1

Dachdeckung: Zement-Bims-imprägnierte Säcke.
Unterkonstruktion: mit Bindfaden gebundenes Rohrgerüst.

Material	Einheit	Menge pro m^2	Einheits-preis (Sh)	Preis pro m^2 (Sh)
Rohr	m	15,00	-	-
Bindfaden	m	10,00	0,01	0,10
Sisal-Säcke	m^2	1,40	1,09	1,53
Zement	kg	9,05	0,08	0,72
Bims	kg	9,05	-	-
Gesamtpreis/m^2				2,35

Experiment 1-2 (b)

Covering: 10% lime stabilized soil without surface protection.
Support: Solid cane structure tied with twine to horizontal cane supports.

Material	Unit	Quantity per m^2	Unit cost (Sh)	Cost per m^2 (Sh)
Canes for support	m	42.00	-	-
Twine	m	10.00	0.01	0.10
Soil	kg	21.70	-	-
Lime stabilizer	kg	1.80	0.07	0.13
Total cost/m^2				0.23

Experiment 1-3

Covering: 10% lime stabilized soil with lime surface coating.
Support: Solid cane structure tied with twine to vertical cane supports.

Material	Unit	Quantity per m^2	Unit cost (Sh)	Cost per m^2 (Sh)
Canes for support	m	42.00	-	-
Twine	m	10.00	0.01	0.10
Soil	kg	20.50	-	-
Lime stabilizer	kg	1.80	0.07	0.13
Lime coating	kg	1.90	0.07	0.13
Total cost/m^2				0.36

Experiment 2-1

Covering: Cement-pumice impregnated sacks.
Support: Cane grid tied with twine.

Material	Unit	Quantity per m^2	Unit cost (Sh)	Cost per m^2 (Sh)
Canes for support	m	15.00	-	-
Twine	m	10.00	0.01	0.10
Sisal sacks	m^2	1.40	1.09	1.53
Cement	kg	9.05	0.08	0.72
Pumice	kg	9.05	-	-
Total cost/m^2				2.35

Experiment 2-2

Dachdeckung: Erd-Kalk-imprägnierte Säcke mit Kalkanstrich.
Unterkonstruktion: mit Bindfaden gebundenes Rohrgerüst.

Material	Einheit	Menge pro m^2	Einheits-preis (S)	Preis pro m^2 (S)
Rohr	m	18,00	-	-
Bindfaden	m	6,00	0,01	0,06
Sisal-Säcke	m^2	1,48	1,09	1,61
Erde	kg	9,80	-	-
Löschkalk				
- als Bindemittel	kg	1,90	0,07	0,13
- als Anstrich	kg	1,80	0,07	0,13
Gesamtkosten/m^2				1,93

Experiment 2-3

Dachdeckung: Zement-Bims-Mischung.
Unterkonstruktion: Rohrgerüst mit Stroh als Zwischenraumfüllung.

Material	Einheit	Menge pro m^2	Einheits-preis (S)	Preis pro m^2 (S)
Rohr	m	16,00	-	-
Bindfaden	m	10,00	0,01	0,10
Zement	kg	11,00	0,08	0,88
Bims	kg	10,50	-	-
Gesamtpreis/m^2				0,98

Experiment 2-4

Dachdeckung: 10% Erd-Kalk-Schicht mit Baumwollgewebe-bewehrtem Kalkanstrich.
Unterkonstruktion: Rohrgerüst mit Stroh als Zwischenraumfüllung.

Material	Einheit	Menge pro m^2	Einheits-preis (S)	Preis pro m^2 (S)
Rohr	m	16,00	-	-
Bindfaden	m	10,00	0,01	0,10
Erde	kg	20,00	-	-
Löschkalk				
- als Bindemittel	kg	1,80	0,07	0,13
- als Anstrich	kg	2,50	0,07	0,18
Baumwollgewebe	m^2	1,10	0,61	0,67
Gesamtpreis/m^2				1,08

Experiment 2-2

Covering: Soil impregnated sacks with protective lime coating.
Support: Cane grid tied with twine.

Material	Unit	Quantity per m^2	Unit cost (S)	Cost per m^2 (S)
Canes for support	m	18.00	-	-
Twine	m	6.00	0.01	0.06
Sisal sacks	m^2	1.48	1.09	1.61
Soil	kg	9.80	-	-
Lime stabilizer	kg	1.90	0.07	0.13
Lime coating	kg	1.80	0.07	0.13
Total cost/m^2				1.93

Experiment 2-3

Covering: Cement-pumice.
Support: Cane grid tied with twine-straw filler between vertical supports.

Material	Unit	Quantity per m^2	Unit cost (S)	Cost per m^2 (S)
Canes for support	m	16.00	-	-
Twine	m	10.00	0.01	0.10
Cement	kg	11.00	0.08	0.88
Pumice	kg	10.50	-	-
Total cost/m^2				0.98

Experiment 2-4

Covering: 10% lime stabilized soil protected with lime impregnated cotton fabric.
Support: Cane grid tied with twine-straw filler between vertical supports.

Material	Unit	Quantity per m^2	Unit cost (S)	Cost per m^2 (S)
Canes for support	m	16.00	-	-
Twine	m	10.00	0.01	0.10
Soil	kg	20.00	-	-
Lime stabilizer	kg	1.80	0.07	0.13
Cotton fabric	m^2	1.10	0.61	0.67
Lime coating	kg	2.50	0.07	0.18
Total cost/m^2				1.08

7. ZUSAMMENFASSUNG UND SCHLUSSFOLGERUNG

7.1 Mögliche Lösungen

Das Dach, eine scheinbar einfache, individuelle Baueinheit, wird zu einem sehr komplexen Element, wenn man bedenkt, auf wieviele Arten es studiert und verbessert werden kann. Die Art und Vielfalt von Lösungen für das Dachproblem kann so fast unendlich variieren, wie die folgenden Überlegungen zeigen:

- Mögliche Lösungen können entweder Verbesserungen bestehender Systeme, vollkommen neue Entwicklungen oder eine Kombination von beidem sein.
- Sie können Teile des Daches betreffen (Unterbau, Abdeckung), das ganze Dach oder gewisse physikalische Eigenschaften (z.B. thermische und akustische Eigenschaften, Stärke, Lebenserwartung).
- Verbesserungen und Neuerungen sind möglich bei Materialien, Entwurf und Baumethoden.
- Aspekte der verbesserten Materialien können jegliche Bearbeitungsphase (von der Beschaffung von Rohmaterialien über Vorbehandlungen bis zum endgültigen Aufbau auf der Baustelle), Elementgröße, Form und Oberflächenbehandlung, umfassen.
- Entwurfsaspekte können sein: Kostenreduzierung, Verbesserung der Erdbeben- und Wirbelsturmsicherheit sowie Innenraumklima und Aussehen.
- Verbesserte Konstruktionsmethoden können vereinfachte und beschleunigte Verfahrensweisen, Tolerierung von Ungenauigkeiten und ungelernten Arbeitskräften, und doch insgesamt eine umfassende Verbesserung der wesentlichen Eigenschaften der Dachkonstruktion sein.

In Anbetracht der Situation in Zentralamerika hat die Untersuchung vier Typen von Dachdeckungssystemen für Billigwohnungsbau gezeigt, die gegenwärtig in dieser Gegend allgemein gebräuchlich sind. Sie umfassen Strohdächer, mit Rundholz- oder Bambusträgern und Tondachziegeln, verzinkte Stahlbleche oder Asbestzementplatten mit Holzunterkonstruktion.

Wenn man die in diesem Bericht aufgezeigten Daten zusammenfaßt, ergeben sich folgende Mängel an den bestehenden Systemen:

- Stroh:
  Hauptsächlich verwendet wegen seiner niedrigen Kosten; es benötigt jedoch zur Fertigung großen Zeitaufwand und einiges handwerkliches Geschick. Es neigt dazu, Insekten und Ungeziefer anzuziehen, und ist nicht feuersicher.
- Tondachziegel:
  Werden von den örtlichen Bewohnern als das attraktivste Dachdeckungsmaterial angesehen, aber ihre verhältnismäßig hohen Kosten machen deren Anwendung für einen großen Teil der Bevölkerung unmöglich. Das sehr hohe Gewicht erfordert ein schweres Stützsystem, und die Ziegel bilden eine Gefahr bei Erdbeben.

7. SUMMARY AND CONCLUSION

7.1 Possible Solutions

The roof, a seemingly simple, individual unit of construction, becomes a highly complex element when considering in how many ways it can be studied and improved. The type and magnitude of solutions to the roofing problem can thus vary almost indefinitely, as the following possibilities show:

- Feasible solutions can either be improvements of existing systems, completely new developments, or combinations of both.
- They can deal with parts of the roof (substructure, roof cover), the whole roof or certain physical characteristics (eg. thermal and acoustical properties, strength, life expectancy).
- Improvements and innovations are possible for materials, design and construction methods.
- Aspects of improved materials may involve any stage of handling (from obtaining raw materials, via pretreatments to final installation at building site), size of elements, shape and surface finish.
- Design aspects could be reduction of cost, improvement of earthquake and hurricane resistance, as well as indoor climate and appearance.
- Improved construction methods can mean simplified and accelerated operations, tolerance of inaccuracies and non-skilled labour, and yet basically an overall improvement in performance of the roof structure.

Considering the situation in Central America , the investigation has shown four types of roofing systems for low-cost housing to be in common usage in the region at the present time. These include thatched roofs with pole or bamboo supports, and clay tile, galvanized steel or asbestos-cement sheets supported by wooden frames.

Summarizing the data presented in the report, the principal deficiencies of the existing systems are the following:

- Thatch:
  Used principally because of its low cost, but requires considerable time and some manual skills for its installation. Tends to attract insects and rodents and lacks fire resistance.
- Clay tile:
  Considered the most visually attractive roofing system by local inhabitants, but its relatively high cost prevents its use by a large segment of the population. Excessive weight requires a heavy support system, and the tiles represent a hazard during earthquakes.

- Verzinktes Stahlblech:
  Wird wegen seiner einfachen Anbringung, seiner relativ niedrigen Kosten und des leichten Gewichts gebraucht. Hauptprobleme sind die kurze Lebensdauer aufgrund von Oxydation, wenn es nicht durch Farbanstrich geschützt ist (übersteigt die Mittel vieler armer Land- und Stadtbewohner), keine Wärmeisolierung (Hitzeabstrahlung nach innen), sehr hohe Geräuschbelästigung bei starkem Regen, Kondenswasserbildung im Innenraum.

- Asbestzement:
  Wird mehr bei öffentlichen Wohnbauprojekten benützt. Verhältnismäßig schwer, hohe Kosten. Schwieriger zu handhaben und zu installieren, leicht zerbrechlich. Dieselben Kondenswasserbildungsprobleme wie bei verzinktem Stahlblech.

In Anbetracht der oben erwähnten Beobachtungen sollte ein verbessertes Dachdeckungssystem für Zentralamerika folgenden Kriterien entsprechen:

- Weniger Zeit und handwerkliche Geschicklichkeit als für den Bau von Strohdächern benötigen. Umkompliziertere Aufbaumethode als bei Asbestzementdächern.
- Feuerbeständiger sein als Strohdächer.
- Die Eigenschaft, Insekten oder Ungeziefer anzuziehen, vermindern oder ausschließen.
- Bedeutend billiger sein als Tonziegel- oder Asbestzement-Dächer.
- Leichteres Gewicht als Tonziegeldächer haben.
- Die Gefahr von herabfallenden Dachelementen bei Erdbeben vermindern oder ausschalten.
- Weitgehend wie Tondachziegel aussehen, da diese von der örtlichen Bevölkerung bevorzugt werden.
- Frei sein von Korrosionsproblemen wie bei verzinktem Stahl.
- Übermäßige Geräuschbelästigung bei starken Regenfällen mindern oder ausschalten.
- Relativ leicht sein, ohne Bruchgefahr zu handhaben und zu verarbeiten.
- Kondenswasserbildung im Inneren mindern oder ausschalten.

- Galvanized steel:
  Used because of its simple installation, relatively low cost and light weight. Principal problems are its short life due to oxidation unless protected by paint (beyond the means of many of the rural and urban poor), lack of thermal resistance (radiation of heat to interior), excessive noise during rainstorms, and interior condensation.

- Asbestos-cement:
  Used more in public housing projects. Relatively heavy and high cost. More difficult to manipulate and install, can be easily broken. Same interior condensation problems as with galvanized steel.

Taking the above observations into consideration, an improved roofing system for Central America should respond to the following:

- Require less time and manual dexterity for its installation than for thatch roofs. Less complicated installation method than that used for asbestos-cement.
- Better fire resistance than thatch roofs.
- Reduce or eliminate the tendency to attract insects or rodents.
- Significantly less costly than clay tile or asbestos-cement roofs.
- Lighter weight than clay tile roofs.
- Reduce or eliminate danger from falling roof elements during earthquakes.
- Simulate the appearance of clay tile roofing systems, since this is preferred by the local population.
- Free of the rust problems associated with galvanized steel.
- Reduce or eliminate excessive noise during rainstorms.
- Relatively easy to handle and manipulate without breakage.
- Reduce or eliminate interior condensation problems.

7.2 Das ideale Dach

Die Analyse von Dachdeckungssystemen in verschiedenen Regionen, die in den vorhergehenden Abschnitten dieses Berichts erläutert wurden, ermöglicht eine Auflistung der wünschenswerten Eigenschaften eines idealen Daches.

Die Erfüllung aller aufgeführten Kriterien mögen in der Praxis undurchführbar sein, aber je mehr die Eigenschaften neuer Dachdeckungs-Lösungen mit den aufgelisteten übereinstimmen, desto größer sind die Chancen, daß sie größere Aufnahmebereitschaft und Anwendung finden und folglich dazu beitragen, ein wichtiges technologisches Problem beim Hausbau in Entwicklungsländern zu lösen.

Kriterien für Entwurf und Ausführung von Dächern in Zentralamerika
(zutreffend für fast alle Regionen der Dritten Welt)

Entwurf:

- dem Klima und der Umgebung angepaßt
  (in feuchten Gebieten Ausschließen von Wärme durch Materialien mit geringer Wärmespeicherkapazität und durch belüfteten Dachraum, dagegen in trockenen und Hochlandzonen Materialien mit Wärmespeicherkapazität; nicht gänzlich wasserundurchlässig, jedoch in der Lage, Regenwasser schnell abzuführen; helle äußere Oberfläche zur Reflexion der Sonnenstrahlung; Schallisolierung, besonders für starke Regenfälle)
- erdbebensicher
  (entweder monolithisch mit hoher Druckfestigkeit oder flexibel mit hoher Zugfestigkeit und festen Verbindungen; statische Trennung der Dachtragkonstruktion von den Wänden)
- wirbelsturmsicher, besonders in Küstengebieten
  (keine Flachdächer; stabile feste Verbindungen zum übrigen Gebäude; kein loses Material, das schwer oder scharfkantig ist)
- optisch annehmbar
  (keine radikal neuen Formen und Materialien, vorzugsweise Fortführung herkömmlicher Formen mit bedeutenden Verbesserungen bezüglich Konstruktion und Kosten)
- ausreichend dauerhaft
  (mindestens 5 Jahre ohne Wartung, vorzugsweise 20 Jahre mit geringer Wartung)

Ausführung:

- von ungelernten Arbeitern und Selbsthilfe-Bauherren leicht erlernbar und beareifbar
- ohne Bedarf an importiertem, kompliziertem Gerät, das nicht gewartet werden kann (das gebräuchlichste örtliche Werkzeug ist die "machete", ein Messer mit einer 30 - 50 cm langen und 5 - 7 cm breiten Klinge)

7.2 The Ideal Roof

The analysis of worldwide roofing systems discussed in the previous sections of this report permits a listing of the desirable characteristics of an ideal roof.

The fulfillment of all the given criteria may in practice be unachievable, but the more the characteristics of new roofing solutions coincide with those listed, the greater are the chances that they find wider acceptance and application, and consequently help to solve a major technological problem of housing in developing countries.

Criteria for Design and Construction of Roofs in Central America
(applicable for practically all Third World regions)

Design:

- Climatologically and environmentally appropriate
  (in humid areas, exclusion of heat by low thermal capacity materials and ventilated roof space, whereas in arid zones and highlands constructions with heat retaining capacity; not totally impermeable, but capable of shedding rainwater rapidly; light outer surface to reflect solar radiation; sound insulation, especially in heavy rains).
- Earthquake resistant
  (either monolithic with high compressive strengths or flexible with high tensile strengths and rigid bonds; structural separation of roof supports from walls).
- Hurricane resistant, particularly in coastal areas
  (no flat roofs; rigid, strong connections to rest of building; no loose material, which is heavy or sharp cornered).
- Aesthetically acceptable
  (no radically new shapes and materials, preferably continuation of conventional forms with significant improvements in construction and costs).
- Adequate life
  (at least 5 years without maintenance, preferably 20 years with minimum maintenance).

Construction:

- Easily learnt and understood by unskilled workers and self-help builders.
- No necessity of imported, complicated equipment which cannot be maintained (Most common local tool is the "machete", a knife with a 30 to 50 cm blade length and 5 to 7 cm width).

- in der Lage, Ungenauigkeiten zu tolerieren und keine komplizierten Qualitätstests zu erfordern
- schnell realisierbar mit minimaler Menschenkraft (z.B. zwei oder drei Personen, die etwa vier oder fünf Tage arbeiten)
- zu beliebiger Jahreszeit durchführbar

Materialien:

- örtlich verfügbar, ohne lange Transportwege, in gesunder Relation zu den finanziellen und technischen Mitteln der Bevölkerung (z.B. ohne Pkw-Transport, Entfernung nur so groß, daß das Material von einem Mann getragen werden kann)
- mit möglichst geringem oder vorzugsweise ohne Gebrauch von importierten Bestandteilen, oder solchem Material, das beispielsweise auf Rohöl basiert (mit steigenden Preisen und abnehmenden Vorräten)
- erneuerbar oder in unbegrenzter Menge verfügbar
- billig oder kostenlos (d.h. ohne weiteres für Bewohner erschwinglich)
- mit vorhandenem einfachem Werkzeug leicht bearbeitbar
- nicht zu schwer, so daß zwei oder drei Männer ein Dach bauen können
- frei von giftigem Material, dos vom Regen abgewaschen werden und die Umgebung verseuchen könnte
- unanfällig für Insekten, Vögel oder Ungeziefer sowie für Pilze
- feuerbeständig oder zumindest feuerhemmend
- für die klimatischen und Umweltbedingungen gut geeignet
- resistent gegen übermäßige Regenwasseraufnahme, jedoch nicht vollkommen wasserundurchlässig (besonders Dachunterseite), um Kondenswasserbildung zu verhindern
- geräuscharm bei schweren Regenfällen
- stoßunempfindlich (z.B. Hagelkörner) und fähig, das Gewicht einer auf dem Dach arbeitenden Person zu tragen
- ganz oder teilweise aus Abfallmaterialien, aber nicht denjenigen, die anderweitig verwendet werden können (z.B. Bagasse, Reis- oder Kokosnußschalen, die als Brennmaterial benützt werden)

- Should tolerate inaccuracies and not require sophisticated quality tests.
- Should be quickly erected with minimum manpower (eg two or three people working about four or five days).
- Should be possible to build any time of the year.

Materials:

- Locally available, no long transport distances, in accordance with the financial and technical means of the people (eg without motorized transport, maximum practical carrying distance for a man).
- Minimum use of, or preferably no imported material, or such based on fossil oils (with rising prices and diminishing supplies).
- Renewable or available in unlimited supply.
- Cheap or no cost (ie well within the means of the occupants).
- Easily handled with available, low technology equipment.
- Not too heavy, so two or three men can build the roof.
- No poisonous material, that can be washed off by rain and contaminate the surroundings.
- Materials that do not encourage nesting of insects, birds or rodents, or promote fungal growth.
- Fire resistant or at least fire retarding.
- Good thermal performance, with respect to the given climate and environment.
- Resistant to excessive rainwater absorption, but not completely impermeable (especially on the underside of roof) to avoid development of condensation.
- Not noisy during heavy rains.
- Resistant to impact (eg from hailstones) and capable of supporting weight of a person working on the roof.
- Possible use of waste materials, but not such that already have other uses (eg bagasse, rice and coconut husks used as fuel).

7.3 Schlußfolgerung

Das vorliegende Forschungsprojekt wurde initiiert, um die Probleme und Möglichkeiten von billigen Bedachungssystemen zu erfassen und grundlegende Informationen über Bedachungssysteme in verschiedenen Teilen der Welt sowie gezielte Daten über die Situation in Zentralamerika zu sammeln. Dies muß als wichtiges Einführungsstadium angesehen werden, von dem Impulse und Ideen abgeleitet werden können bei der Suche nach neuen geeigneten Bedachungsmöglichkeiten in Zentralamerika.

Die Experimentierphase des Projektes war vor allem einleitender Art. Sie wurde durchgeführt, um besonders solche örtlich verfügbaren Materialien, die gegenwärtig nicht für Dachkonstruktionen verwendet werden, zu testen und ihre Anwendungsmöglichkeiten für billige Bedachungssysteme auszuwerten. Da die Entwicklung, Verbesserung und Implementierung neuer Dachdeckungssysteme ein schwieriger und langer Prozeß ist, zeitigten diese anfänglichen Experimente kein unmittelbar annehmbares neues Dachkonzept. Die bis jetzt erreichten Ergebnisse der Tests mit Zement-Bims und Kalk-stabilisierten Erd-Mischungen, kombiniert mit verschiedenen Verstärkungsmaterialien und einfachen Bambus- oder Rohrkonstruktionen, erscheinen jedoch vielversprechend genug, um weitere Forschung auf diesem Gebiet zu rechtfertigen.

7.3 Conclusion

The present research project was conceived to obtain an understanding of the problems and possibilities of low-cost roofing and to collect basic data on roofing systems in the world in general, as well as specific information on the situation in Central America. This must be seen as an important introductory stage, from which impulses and ideas may be derived in the search for new appropriate roofing in Central America.

The experimental phase of the project was of a preliminary nature conducted primarily to screen locally available materials not currently used for roof construction to evaluate their potential as elements for low cost roofs. Since the development, improvement and implementation of new roofing systems is a difficult and long process, these initial experiments, as expected, did not result in an immediately acceptable new roofing concept. However, the results to date of the tests performed on cement-pumice and lime stabilized soil mixtures combined with diverse reinforcing materials and simple bamboo or cane support structures, appear sufficiently promising to warrant further research in this field.

Roof tent

From Wikipedia, the free encyclopedia

A **roof tent** is an accessory which may be fitted to the roof of a motor vehicle which allows the users to sleep in relative safety and comfort above the vehicle, and leaves the internal load-space free. The first example of roof-tents appeared in Western Europe in the 1930s.[1]

ARB Simpson II roof top tent on a Nissan Patrol.

Roof tents are particularly seen on expedition-prepared four wheel drive vehicles such as Land Rovers, but can be fitted to almost any vehicle. Generally they will mount to a vehicles roof rack or aftermarket roof bars. They are particularly popular in Italy and one manufacturer advertises them using photographs of their devices fitted to cars as small as the Fiat Panda.

Designs and styles

Gordigear roof tent on a Toyota Land Cruiser.

Roof tents have traditionally taken the form of a conventional ridge-pole tent which can be folded into a compact package, resting on marine plywood, and mounted on a roof rack. Beginning in 1958, more modern tent designs appeared - housed in a waterproof, moulded fiberglass or carbon fibre box, and are erected and taken down more quickly using a simple crank-operated cantilever arrangement or gas rams that automatically erect the tent when the latches are released. In 2003 a French manufacturer introduced another design of simple and lightweight tents, resembling modern sprung-pole types of ground tent.

1 INTRODUCTION

This report is an output from a 27 month research contract (R7833) for the UK Department for International Development and describes work done during the 4 month prototyping phase of that project. The prototyping phase has developed out of the practice descried in the report to the DFID "R1, Very-Low-Cost Domestic Roofwater Harvesting in the Humid Tropics: Existing Practice" and the constraints identified in "R2, Very-Low-Cost Domestic Roofwater Harvesting in the Humid Tropics: Constraints and Problems". The work itself was carried out by the DTU along with members of the Lanka Rainwater Harvesting Forum in Sri Lanka, Water Action in Ethiopia and ACORD in Uganda.

The Sri Lankan portion of this work would not have been possible without the facilities and kind assistance of the Nation Builders Association. In particular we would like to thank Mr Adikarum, Mr Amarasinge, Mr Widasecara and Mr Siripala for their help, insight and patience during our time there.

1.1 The need

Surveys carried out in the initial phase of the project have pointed to cost as the number one constraint facing users adopting roofwater harvesting so if it is to become an affordable option for poor people in developing countries, the cost of systems must be reduced.

In R2 a methodology for cost reduction of roofwater harvesting systems was discussed. The method revolved around the building of a rainwater harvesting service framework as shown in Figure 1.1 focusing on the quality of structure as well as the quantity of water delivered. By reducing the structural quality to a level closer to the quality of housing found in poor areas, large savings can result.

Figure 1.1: Service framework for rainwater harvesting systems

a. Framework

b. How current systems map onto the framework

In reducing the quality, however, there are a number of critical functional constraints that should be regarded as a minimum specification:

- Gutters should deliver a good fraction of the water falling on the roof – dependent on the local rainfall, roof size storage size and demand pattern
- The tank should not have excessive loss through seepage or evaporation – <5% of the water drawn from it

- The tank should not present an excessive danger to its users, either by their falling in or by the tank failing violently
- The water must be of a quality consummate with its intended use – water that is used for drinking requires a certain care in transport and storage:
  - The catchment area should be smooth and free from accumulated debris
  - The water should be filtered to remove gross impurities or the first flush removed
  - The tank should be covered to prevent entry of light, and sealed against intrusion by vermin
  - The tank should be ventilated to prevent anaerobic decomposition of any washed-in matter

1.2 Methods of cost reduction

The methods used to reduce the cost of rainwater harvesting systems are covered in report R2, the methods described are:

- Material reduction (Improved formwork, Shape optimisation, Function separation)
- Material substitution (Using cheaper materials, use of "free" materials)
- Mass production
- Use of existing containers

1.3 Basis for cost comparison

Costing "rainwater harvesting systems for the poor" is more complex than simply adding up component costs on a bill of materials. Some materials are only available at a cost through purchasing channels, while others are available at no cost if one is willing to gather them. This report will group materials and labour into the following categories:

a. *Economic materials*; materials relying on industrial processes – in their purchase cash will be removed from the area

b. *Local economic materials*; materials which must be bought but where production is from local sources – the cash will remain in the community

c. *Skilled labour*; labour that must be paid for

d. *Local materials*; materials that can be gathered from the land – they may or may not have an economic value but tend to be freely available

e. *Householder labour*; labour that can be provided by the household – it may be skilled, but in locally used techniques (such as wattle and daub construction).

For the poor the latter two costs may be heavily discounted when compared to any cash outgoings, and consequently they will be are separated from the first three 3 in costings presented in this report.

Household labour is often ignored in costing programmes aimed at the poor, however this may become unrealistic if the household labour contribution becomes burdensome. Another approach is to allocate an opportunity cost of 50% of the unskilled labour rate to such a contribution to reflect the loss of time to the household. The real value of their time to a householder should lie between these two figures, so both will be quoted in this report They are referred to as "HH labour discounted" cost and "HH labour ignored" cost. A total cost with no discounting is also included for reference.

2 TANKS

2.1 Current state-of-the-art

Current practice is comprehensively described in report R1 so only a brief summary of current best practice will be given here as a baseline from which to judge new developments. Water storage forms the largest single cost component of a RWH system and so is the most likely candidate for cost reduction. Current state-of-the-art for storage tanks in developing countries is ferrocement construction, either based on a fixed solid mould or on an open framework. Generally, a solid mould results in a cheaper tank, as the wall thickness of the tank can be more tightly controlled and work is done against an inflexible surface. Open frameworks have the advantage of allowing greater flexibility in tank size but at the cost of plastering work taking place against an elastic backing which lets some mortar through resulting in greater and more variable wall thickness and a higher cost per tank. Tanks are also made from bricks which can reduce costs by material substitution but the savings are often not great although more of the money remains in the community. A graph of current costs of various techniques in the three study countries is given in Figure 2.1.

Figure 2.1: Tank costs

Notes: Points represent costs with household labour discounted, error bars represent the extremities when household labour is included in full or ignored altogether

Lines slopes correspond to a cost:capacity sensitivity of 0.6

A cost sensitivity to volume of 0.6 – 0.7 is the norm, so designs can be usefully compared over a wide range of capacities. The Solid blue lines represent the bounds of normal state-of-the-art. the dotted red line represents the lower limit of a region populated by “exceptional” designs such as the Thai jar and the Ugandan tarpaulin tank. It is this region that forms the target cost range. Tanks developed during the prototyping phase of the programme fall mainly into the benchmark range as shown in Figure 2.2.

Most of the designs also have a greater reliance on household labour and local materials so compulsory cash costs are kept lower still (as indicated by the bottom extent of the error bars).

Figure 2.2: cost comparison of tanks developed during the prototyping phase

2.2 Below-ground designs

Below ground designs are the mainstay of low cost tank design. If built in stable soil, the ground itself will act as a stiff spring taking much of the load, reducing the role of the lining material to waterproofing. In these circumstances, tank wall thicknesses can be very small and materials that have good waterproofing properties but suffer from a low structural strength (such as polyethylene sheet) can be used.

Tube tank

The tube tank was originally developed by the DTU in July 2000 (Rees & Whitehead, 2000), as part of a technology development project funded in part by the Morris Laing Foundation. The design was based around a widely available plastic tube of about 500 microns thickness sold by the metre on a roll of 3ft width. The cost of this tube is £0.38 in Sri Lanka, £0.54 in Ethiopia and £0.40 in Uganda. When opened, the tube forms a cylinder of Ø54cm resulting in a volume of 0.23m^3 per metre length. The cost of storage, is therefore only £1.66, £2.33, £1.75 (SL, Et, Ug) per m^3 of storage for the tube itself. The original design (see Figure 2.3) was based on the partially below ground principle where most of the tank was below ground, but about 1m protruded as a brick parapet, avoiding stormwater ingress

and providing a visual presence for the tank. A hole was dug to accommodate the tube and a bag was formed by folding and tying off the end. The bag itself was fixed between two courses of bricks and an overflow pipe was fitted in a hole in the bag and sealed with a small amount of cement.

Figure 2.3: Original tube tank design. (all pictures from (Rees & Whitehead, 2000))

General arrangement of tube tank Mk 1

Digging the hole

Bag tying

Overflow arrangement and fixing of the bag between brick courses

The design was fairly successful and several of the tanks are in service however it has some problems, most which have become apparent after a year of use:

- The cost of the parapet wall dominates the overall tank cost and forces the design to compete directly with more robust and desirable designs such as the ferrocement jar
- The hole is difficult to dig
- The tied joint at the bottom can leak
- The liner is extremely difficult to remove if it is punctured – those that do leak have not been repaired
- The overflow can leak resulting in accumulation of water between the bag and the excavation walls

The new design (see Figure 2.4)addresses these problems by including the following changes:

- A more classic underground design using a precast concrete cover reduces the cost. The cover itself is similar to the arrangements found on some handpumps and so should be familiar to use. It is made using similar casting techniques to pit latrine covers (sanplats).
- The tube has been folded in two, eliminating the tied joint, making the hole 40% larger and consequently, easier to dig
- The tube itself is easily replaceable by using a retaining ring and binding wire to hold the tube in place.
- A variant folds the tank into a “L” shape reducing the depth of the excavation and replacing the vertical hole with a trench

Figure 2.4: Modified tube tank design.

General arrangement of tube tank Mk 2

Retaining ring

Overflow

Horizontal folded tube tank being filled

With these modifications, the design is extremely inexpensive at less than £18 for a 700l tank and £26 for a 2m^3 folded tank. Although the prototypes were made using in-situ casting in the ground, the slab has designed with pre-casting in mind and so is well suited to factory production where savings of up to 50% can be made by drastically reducing labour content.

The tank design is also ideally suited to rapid implementation projects such as refugee camps; if the excavation is done by the householders, an agency can simply transport a number of prefabricated parts and each tank can be assembled within an hour.

Tank size is determined by hole depth so the deeper a household digs, the larger the store, extra storage is relatively cheap as the cost of the tank is dominated by the concrete slab. The alternative horizontal folded design is more suited to less stable soils as the excavation itself is about 60cm deep and can be tapered if necessary, however the cost is higher due to the need to cover the trench over. Costs of several capacities of each type of tube tank are shown against benchmarks in Table 2.1.

Table 2.1: costs of tube tanks

a. vertical

Capacity (m^3)	0.6	0.8	1.0
Total	£16 – 17	£16 – 17	£17 – 19
Total (HH labour discounted)	£14 – 16	£15 – 17	£16 – 18
Total (HH labour ignored)	£13 – 15	£14 – 17	£16 – 18
Target range	£9 –15	£11 –18	£12 –20

b. horizontal

Capacity (m^3)	0.8	1.2	1.6	2.0
Total	£17 – 18	£20 – 22	£21 – 24	£23 – 26
Total (HH labour discounted)	£17 – 18	£20 – 21	£20 – 23	£23 – 26
Total (HH labour ignored)	£16 – 17	£19 – 21	£19 – 23	£22 – 26
Target range	£11 –18	£13 – 22	£16 – 26	£18 – 29

Thin shell cement slurry lining

Neat cement is about 40% stronger and twice as flexible as mortar. It is also almost completely impermeable, making the material ideal for the construction of very thin shells to line pits. Initial experiments on a 1m depth pit of Ø1.5m revealed leakage of less than 10 litres/day and the surface showed no cracks. A larger pit of 3m depth was also tried, however the cement was applied without

due care and cracks developed. The leakage from this pit is 80 litres/day, however no additional cracking has been observed as a result of the significant head of water acting on the shell.

The thin shell cement lining technique can result in material economies of up to 50% when compared to conventional mortaring, however the care with which it must be applied to the soil may make it unsuitable to unsupervised (free market) construction at a local level.

Direct application of mortar

It is common practice to put mesh in an underground tank when lining with mortar. Typically this takes the form of a layer or two of chicken wire. The given reasons are that it:

- adds strength
- provides a surface upon which to plaster (lath)
- Reduces cracking

Looking at the first of these reasons, a single layer of chicken mesh will have an in-line volume fraction less than 0.2% when compared to the mortar (assuming a 1cm mortar layer), so its contribution to the strength of the composite is fairly minimal (about 20% using the law of mixtures). Of course, the strength of an underground tank is mostly from the reaction of the soil itself.

The second may be true, but the initial layer of mortar is usually applied to the hole *adding* the mesh (indeed placing mesh directly on the soil is risky as it will certainly corrode from contact with moist soil). Further layers can be built up by scoring the original thus providing keys in the mortar itself. Such scoring is also simple to add to a hard soil and should provide a good keying for mortaring.

Crack reduction can be a useful property, particularly in tanks with large surface areas, however in smaller, domestic tanks cracking is not big problem as witness the popularity of mortar tanks in Thailand.

Thus the supposed advantages of using mesh may be insubstantial in this application and are certainly small compared to the advantages of using the strength of the soil wall.

Conversely, the mesh itself will cause problems when added to a concave surface such as the inside of a hole. The problem is basically one of overconstraint. If one considers, for the sake of argument a flexible sheet placed inside a cylinder. It can be either just the right size, too small or too big. If it is too big, the loose mesh forms bubbles, losing the benefit of the earth wall's support, if it is too tight it will stretch tight across the wall rather than following the curve, resulting in voids. Adding fixing points is the usual solution to these difficulties but this often simply turns one large problem into several small ones. The more fixings, the better the fit but also the greater likelihood of human error – the result can even be areas of too tight mesh next to bubbles of too loose mesh.

Directly applying mortar to the walls has proven to be a simple technique to apply in the field. A thin layer of 1cm can be applied with ease and with good quality control. The mortar itself has no need for high strength so can be as lean as 1:8 (cement:sand) in a good soil. Waterproofing is provided by a thin cement slurry applied while the mortar is wet. Several tanks have been built using this method to depths of up to 2.5 meters with no visible cracking and lower leakage than evaporation. The direct application of lean mortar with a slurry coat is the basis for two interrelated designs of tank, the below-ground cement tank with a cheap roof based on organic material and the partially below ground tank with a ferrocement dome.

Below-ground cement tank with organic roof

Ring beam with trench

Shuttering for pump and overflow mounting

low-cost tank cover under construction

Finished tank with cover in place

As the cost of the below-ground waterproof tank is reduced, the cover of the tank becomes the dominant cost. Organic roofs are used on many buildings in poor households and so the skills to build them are common. The materials themselves also tend to fall into the "gatherable" class. To put an organic roof onto a water tank, however, a number of precautions must be taken.

- The organic material must not fall into the tank and contaminate the water
- Runoff from the organic roof will be of low quality and so must not be allowed to enter the tank
- The roof must provide a good barrier to vermin entry, especially as some creatures make their homes in thatch.
- The wooden supports must not be exposed to the humid atmosphere inside the tank which will make them liable to rot
- To aid bacteriological die off, the roof must provide a good barrier against sunlight entering the tank

A polyethylene barrier fulfils the need to protect the organic matter from moisture and also to protect the water from falling debris. If the joining is handled well, it can also act as an excellent seal – completed by the use of inner tubes around the rim. Prevention of water entry can be afforded by the use of a sloped ring beam which will divert the water away from the tank and into a drainage channel.

Below-ground tanks also need care with avoiding floodwater ingress and also with overflow arrangements. The new design uses a syphonic overflow by employing an upwardly facing elbow connected to an outflow pipe which leads either to a nearby slope or to an infiltration pit. Stormwater ingress is handled by digging a channel around the ring beam to a width and depth determined from the runoff.

The overall combination of direct mortar application and low cost roof yields a tank that uses very little material but is quite householder labour intensive. The costs for the tank are shown in Table 2.2.

Table 2.2: Cost of underground mortar tank with organic roof

Capacity (m^3)	2	4	5	8
Total	£28 – 40	£32 – 43	£33 – 46	£37 – 51
Total (HH labour discounted)	£25 – 29	£29 – 35	£30 – 36	£34 – 43
Total (HH labour ignored)	£19 – 23	£22 – 29	£23 – 29	£26 – 3`5
Target range	£18 – 29	£26 – 43	£26 – 48	£38 – 63

Partially below-ground tank with ferrocement dome

Lining the pit

Fixing the frame for the dome

first layer of mortar for the dome

Finished tank

A solution to the overflow and floodwater problems of an underground tank is a partially below ground design where most of the tank is underground takes advantage of the economies to be found from soil support but with some of the tank protruding. Partially below-ground tanks form a bridge between underground tanks and above-ground tanks. They are somewhat more expensive than purely underground tanks, as the above-ground section can cost 3-4 time more per unit volume than the underground section. The Below-ground cement tank can be upgraded to form partially below-ground tank by simply adding a ferrocement domed cover. The dome uses a removable frame that leaves behind only wire mesh as reinforcement. The mortar can either be applied without any other formwork by using one person outside to apply the mortar and one person inside to provide a backing (the addition of a small amount of sacking fibres to the mortar was found to help this process) or by making a temporary formwork from cardboard. The dome can be built when the tank is first commissioned or added later when more funds are available. The finished tank is slightly more expensive per litre than the organically roofed over tank but will require less maintenance. Costs for the tank are shown in Table 2.3.

Table 2.3: Cost of partially below-ground tank

Capacity (m^3)	3	5	7	10
Total	£37 – 43	£41 – 51	£49 – 62	£54 – 71
Total (HH labour discounted)	£35 – 39	£39 – 47	£46 – 57	£51 – 65
Total (HH labour ignored)	£30 – 35	£34 – 43	£40 – 52	£43 – 59
Target range	£22 – 37	£29 – 48	£35 – 58	£43 – 71

2.3 Above-ground designs

Above ground designs are generally more popular than below ground solutions, however the cost is often also higher as the tank must now cope with the full force of the water pressure acting on it. The principle of functional separation allows some scope for cost reduction. Waterproofing can be done by either mortar or a liner.

Fabric tank

end of fabric tank with bracket

top sheet showing rubber seal

completed fabric tank

An above-ground tank is almost essential in poor crowded urban areas as the ground can be very contaminated. Ideally, a tank should also be fairly portable as tenure in such communities can often be insecure and many squatter communities live under constant threat of being moved on. The fabric tank goes some way to fulfilling these needs by providing a tank with a small footprint, protruding only 45cm from the dwelling. The tank can also be collapsed down into a long, thin package for transport. A polyethylene tube is placed within a fabric sleeve which is hung on a framework. The fabric takes the pressure load while the polyethylene provides waterproofing.

Unfortunately, the tank has proved problematic as the fabric itself stretches and puts high loads on its fixings which then fail. The fixings could be made stronger and more expensive fabrics should stretch less, however they will make the tank unaffordable.

Crate tank

lid with hole for inlet

delivering the crate to the household

Internal configuration

Finished tank in use

A similar design to the fabric tank has a wooden crate forming the load-bearing structure. The design has the same small footprint as the fabric tank but is not as portable as it can only easily be knocked down into its component walls. It is, however, much better protected from accidental damage than the fabric tank. The design is similar in concept to the tube tank with a retaining ring holding the top of the tube to the top of the tank providing an inlet. The tube than folds around and the other end is attached to the overflow. A tap is attached at the bottom of the “U” and sealed with bitumen. The outlet and overflow can be on any of three sides of the tank to help it fit in with its location. The total cost of the tank is slightly higher than the target range, however the need for a slender profile and portability may make the tank usable in areas where cheaper alternatives will be inappropriate. The manufacture of the tank employs only skilled labour but is very portable (deliverable) so it lends itself to mass production at a central location which could reduce the cost.

Table 2.4: Cost of crate tank

Capacity (m^3)	0.8
Total	£23 – 28
Target range	£11 – 18

Wattle and daub tank

Bamboo frame

Detail of manhole

Mud blocks used for testing

Finished tank

A simple way of producing an above-ground tank with the economy of a below ground tank is to bring the ground up. Several earth technologies have been used in building for millennia and such techniques are often the mainstay of housing for the poor. Wattle and daub is a widespread practice for building from earth, particularly when householders their own homes. The technique uses unmodified mud to fill a frame structure made from roundwood. The materials necessary for this type of constructions are all in the "gatherable" class so cash costs are extremely low, being limited to the liner and plumbing.

A small sample of mud blocks from different sources were tested for tensile strength and it was found that they lay in the fairly narrow range of 730kPa to 900kPa with ant-hill mud generally at the higher end. This compares poorly with 2 – 5MPa for Portland cement mortar so walls have to me made quite thick – typically 15 to 20cm. Initial tests used cement as a liner, however the mud structure expands slightly under load and the lining cracked resulting in leakage and damage to the mud walls. The use of a plastic liner has proved much more satisfactory.

Table 2.5: Cost of wattle and daub tank

Capacity (m^3)	1.25	2	3.5	5
Total	£25 – 37	£27 – 40	£31 – 45	£34 – 48
Total (HH labour discounted)	£22 – 26	£24 – 29	£27 – 32	£30 – 35
Total (HH labour ignored)	£16 – 18	£17 – 20	£20 – 23	£22 – 26
Target range	£14 – 23	£18 – 29	£24 – 40	£29 – 48

Rammed earth

The use of rammed earth provides a stiffer structure than wattle and daub and can be rendered internally with mortar. The earth can also be stabilised with Portland cement to provide a better wet strength than with mud construction. The DTU has done some previous work with this technique to build cylindrical tanks (Rees, 2000) however they proved difficult to construct due to movement of the round mould during manufacture. To combat this, trials have taken place to develop a rectangular tank using traditional corner jointing methods and reinforcing. The trials are thus far incomplete but show some promise for a controllable product that can be used in sandier soils where mud construction is impossible.

Connected drums

Drums form an easily accessible form of storage and many households already have at least one drum performing various duties, among them water storage and even opportunistic rainwater collection. Very few households employ more than one such drum however despite the extra water this could provide. Drums also have a small footprint and are light enough to be portable. They do suffer from problems such as the possibility of residual toxicity and solar heating of the water through the metal.

Several configurations of 2 or 3 drums have been tried, including two forms of vertical connection and one horizontal one. The pros and cons of these are detailed in Table 2.6. Initial Cleaning of the drums is usually done by using a locally produced caustic soda, however there is still some uncertainty about its effectiveness.

Table 2.6: pros and cons of different drum configurations

Type	Pros	Cons
1. Vertically stacked drums connected by means of pipefitting.	• Doesn't require welding or electricity. • The piped outlet allows incorporation of a slow-sand filter • Small footprint	• There is some leakage in the lower drum between the lid and circular clamp.
2. Vertically stacked drums connected by means of welding.	• The number of fittings is reduced • There is no leakage in the system • Small footprint	• Depends on the availability of a welder.
3. Horizontally placed drums connected by means of pipefitting	• An unlimited number of drums can be connected without leakage from the top • Repeated filtering provides different grades of water. • Doesn't require welding or electricity	• The required space is relatively higher compared to others and thus the material for the plinth is greater

The final design uses two vertically stacked drums with welded seams to prevent leakage and an internal slow sand filter. As the slow flow through the filter could reduce the storage, particularly in heavy storms, an optional separate tank has been added to catch this overflow. The overall cost is quite high by very-low-cost standards but still within state-of-the-art boundaries especially considering the design incorporates quite sophisticated filtering.

Table 2.7: Cost of drum configurations[1]

Type	1	2	3	final
Number of drums	2	2	3	3
Capacity (litres)	340	420	620	540
Total	£30	£31	£36	£38
Target range	£7 – 11	£7 – 12	£9 – 15	£9 – 14
Upper limit of state-of-the-art	£41	$47	£58	£53

Note: Costs are based on Ethiopian experience

Several connected jerry cans

Many households already have a fair storage in the form of several jerrycans. The cans themselves are inherently portable and can be distributed throughout the dwelling to save space and so are a good solution for crowded urban areas. The requirement is for a system of plumbing to connect these cans together to form a continuous storage. The cans then fill up in turn with the water quality improving in

each successive can. A system of siphons empty the plumbing into the last can or to an overflow so there will be no leakage when a can is removed for use, however the problem of accidentally leaving a can out of the chain (with disastrous consequences when it rains) is still unsolved. The cost of the cans themselves is also a problem and could make the system uneconomic unless the household already has a reasonable number available.

Cascade of water jars

Many households use water jars for water collection. These jars are well suited to stacking in an array. The water runs down the outsides of one jar into the mouth of another with quality improving as it moves down the cascade. The rounded jars do allow the water to progress unhindered to the next, however the overall storage is quite low at 75 litres. The framework necessary is also quite expensive and puts the entire array into the higher end of the state of the art at about £16. the jars themselves are fairly low in price, however and so a cheaper frame (e.g. a suspended chain) could make the system more economic but it will never be a very-low-cost option.

3 ROOFS

Another difficulty with roofwater harvesting is its reliance on an impermeable roof. Penetration of corrugated iron sheet roofs is growing rapidly and the costs are becoming competitive with professionally thatched roofs, however many poor houses in developing countries still have organic roofs. The reasons for this include cost, particularly where the roof is made by the householder, insulation and ventilation of the smoke from cooking fires.

There are five strategies for utilising organic roofs for rainwater harvesting;

1. Use the water for secondary processes
2. Treat the water
3. Cover the roof with an impermeable cover
4. Build a separate roof structure in the household compound
5. Use a nearby public building

Covering the roof and roof structures are the most obvious technical solutions, however, it was found that covering an organic roof with an impermeable barrier can cause problems to the roof itself, as water cannot evaporate presenting ideal conditions for mould growth, and the ultimate rotting of the structure. The runoff water quality from a number of materials for that might be employed to either to cover a roof or on a separate structure was measured. The materials tried were corrugated iron sheet, corrugated asbestos sheet, polypropylene sacking, tar sheet and palm-leaf organic roofing (*cadjan*).. A typical set of runoff quality results is shown in Figure 3.1. The characteristic runoff quality follows a

power law decay with different materials having different starting points. Organic roofs predictably having the worst water quality while tar sheet, which is readily available and inexpensive has a good runoff characteristic, in line with asbestos but the water does contain petro-chemicals whose levels and rate of decay has not yet been quantified. Turbidity for the GI sheet is below the minimum level that can be discerned with the Del Agua turbidity meter used for this measurement and is therefore below the 5NTU level for turbidity set by the WHO (WHO, 1997)

Figure 3.1: Runoff quality of different roof types

4 GUTTERS

Guttering on a very-low-cost roofwater harvesting system can take up a substantial amount of the cost so its optimisation is important here. Typical state-of-the-art gutters in developing countries tend to be quite expensive with a typical 10m length costing from £10 to £25. Some work has been done in East Africa with vee shaped gutters which have a typical cost of £8 for a similar length. Research at Warwick on optimising gutter size based on carrying capacity suggests that a vee shaped gutter of only 7.5 cm width is sufficient to carry water from all but the most severe downpours and will deliver more than 90% of the water it catches. Such a small gutter should cost less than £3 for a 10m run.

Water interception is a slightly more difficult issue. Water often has to fall some distance from the roof to the gutter and is thrown from the roof different distances depending on the intensity of the downpour. It can also be blown by wind in unexpected directions. Two solutions for this have been tried.

Figure 4.1: Gutters configurations

a. G-shaped gutter

b. extended vee

The first (Figure 4.1a) is a complete solution that captures the water at the end of the roof and directs it into the gutter below. The gutters are also very quick to install as the slope is determined by a variable manufactured length of vertical support (between A and B) so no adjustment is necessary. Cleaning is also simple as the inside edge is open for a brush all the way along its length. Problems with the gutter appear when the length to be guttered is longer than 5m or when thick roofs need to be accommodated. Under these circumstances the vertical support becomes very long and can flex causing the gutter to spill. This can be alleviated by using support wires with the loss of some ease of cleaning, however as the vertical support can use a substantial amount of material, the gutter starts to become expensive at over £9 for 10m.

The second uses the concept of a “upstand”, where one side of the gutter stands proud of the other, effectively raising the catchment height of the gutter. In the design the usual square gutter has been simplified to a vee and the upstand is merely an extension of one arm of the vee. This extends the catchment of the gutter upwards and moves the centre of the catchment out from the roof edge better matching the profile of water flowing from a roof. The gutter is extremely cheap (less than £3.50 for a 10m run) and can be applied to any sized roof without the need for a facia board. Like all suspended gutters, the design does need adjustment to maintain the slope and the suffers from guy wires obstructing cleaning.

5 CONCLUSION

The cost of rainwater harvesting systems can be reduced by a number of methods several of which have been presented here. The most promising are:

- The use of thin shell cement lining as found in the underground cement tank with an organic roof and the partially below-ground tank with a ferrocement dome
- The use of free materials and local techniques such as wattle and daub construction and organic roofs
- Earth technologies such as wattle and daub and rammed earth
- Mass production methods and the use of plastic linings as used in the tube tank and crate tank
- Incorporation of existing structures such as drums
- Smaller profile, sheet-metal gutters which can incorporate features such as water guides or extended catchment surfaces

Less successful were such techniques as:

- Distributed storage in jerrycans and multiple pots
- Very portable, yet fragile tanks such as the fabric tank

- Over-thin plastering techniques that rely on excessive quality control such as Thin shell cement slurry lining

Special circumstances can also be incorporated at little cost

- Tall thin structures such as the crate tank and vertically stacked drums can be built for crowded urban areas
- Auxiliary roofs can be constructed at little cost as an alternative to poor quality organic roof catchments

But

- Very portable, yet fragile tanks such as the fabric tank
- Roof covering treatments that are built onto an existing roof

Are problematic and cannot be recommended.

National Academy of Sciences – National Research Council
Washington, D.C. 1974

This report has been prepared by a Special Advisory Committee of the Building Research Advisory Board–Division of Engineering–National Research Council in cooperation with the Board on Science and Technology for International Development, Commission on International Relations, National Academy of Sciences, for the Office of Science and Technology, Bureau for Technical Assistance, Agency for International Development, Washington, D.C., under Contract No. AID/csd-2584.

NOTICE: The project which is the subject of this report was approved by the Governing Board of the National Research Council, acting in behalf of the National Academy of Sciences. Such approval reflects the Board's judgment that the project is of international importance and appropriate with respect to both the purposes and resources of the National Research Council.

The members of the committee selected to undertake this project and prepare this report were chosen for recognized scholarly competence and with due consideration for the balance of disciplines appropriate to the project. Responsibility for the detailed aspects of this report rests with that committee.

Each report issuing from a study committee of the National Research Council is reviewed by an independent group of qualified individuals according to procedures established and monitored by the Report Review Committee of the National Academy of Sciences. Distribution of the report is approved, by the President of the Academy, upon satisfactory completion of the review process.

SPECIAL ADVISORY COMMITTEE ON NEW TECHNOLOGY SOLUTIONS TO ROOFING PROBLEMS IN DEVELOPING NATIONS

ALBERT G. H. DIETZ, Professor of Building Engineering, School of Architecture and Planning, Massachusetts Institute of Technology, Cambridge, Massachusetts, *Chairman*

C. E. BUSHNELL, JR., Armstrong Cork Company, Lancaster, Pennsylvania

THOMAS CALLAWAY, Director, Division of Technology and Documentation, Office of International Affairs, U.S. Department of Housing and Urban Development, Washington, D.C.

ERIC CARLSON, Chief, Housing Section, Centre for Housing, Building and Planning, Bureau of Social Affairs, United Nations, New York, New York

J. P. R. FALCONER, Associate Director, Center for Development Technology, Washington University, St. Louis, Missouri

RICHARD L. FRICKLAS, Johns-Manville Products Corporation, Denver, Colorado

ALBERTO GONZALEZ-GANDOLFI, Chief, Building Section, Centre for Housing, Building and Planning, United Nations, New York, New York

PHILIP HUBER, Senior Specialist, Housing and Urban Development, Department of Social Affairs, Organization of American States, Washington, D.C.

J. W. S. DE GRAFT-JOHNSON, Director, Building Research Institute, CSIRO, Kumasi, Ghana

ROBERT G. LINDNER, General Manager, Technical Center, H. H. Robertson Company, Ambridge, Pennsylvania

BRUCE McCARTNEY, Consultant, Reston, Virginia

DINESH MOHAN, Director, Central Building Research Institute, Roorkee (U.P.), India

TRAYON ONETT, Manager, Program Development, Koppers Company, Inc., Monroeville, Pennsylvania

ARNOLD ROSENBERG, Research Director, Construction Products Division, W. R. Grace and Company, Cambridge, Massachusetts

HENRI SCIOVILLE-SAMPER, Chief Urban Development, Inter-American Development Bank, Washington, D.C.

WILLIAM R. TYLER, Manager, Technical Division, Building Industry Sales, Aluminum Company of America, Pittsburgh, Pennsylvania

JUAN B. CABRERO, Chief, Technical Division, Office of Housing, Agency for International Development, Department of State, Washington, D.C., *Observer*

WARREN R. NELLIS, Staff Study Director for Building Research Advisory Board, Division of Engineering, National Academy of Sciences, Washington, D.C.

NOEL D. VIETMEYER, Staff Study Director for Board on Science and Technology for International Development, Commission on International Relations, National Academy of Sciences, Washington, D.C.

BUILDING RESEARCH ADVISORY BOARD

JOSEPH H. NEWMAN, Vice President, Tishman Research Corporation, New York, New York, *Chairman*

HERBERT H. SWINBURNE, FAIA, Partner, The Nolen and Swinburne Partnership, Architects, Engineers, and Planners, Philadelphia, Pennsylvania, *Vice Chairman*

J. NEILS THOMPSON, Balcones Research Center, University of Texas, Austin, Texas, *Vice Chairman*

BRIAN J. L. BERRY, Irvin B. Harris Professor of Urban Geography, University of Chicago, Chicago, Illinois

BERKELEY G. BURRELL, President, National Business League, Washington, D.C.

ANGUS CAMPBELL, Director, Institute of Social Research, University of Michigan, Ann Arbor, Michigan

NORMAN COHN, Chairman of the Board, Urban Investment and Development Corporation, Chicago, Illinois

PATRICK CONLEY, Vice President, The Boston Consulting Group, Inc., Boston, Massachusetts

PATRICK J. CUSICK, JR., President, Greater Hartford Community Development Corporation, Hartford, Connecticut

WALTER S. DOUGLAS, Partner, Parsons, Brinckerhoff, Quade and Douglas, New York, New York

ROBERT MARTIN ENGELBRECHT, Robert Martin Engelbrecht and Associates, Architects, Planners, Researchers, Princeton, New Jersey

ARTHUR J. FOX, JR., Editor, Engineering News Record, McGraw-Hill, Inc., New York, New York

ROBERT A. GEORGINE, Secretary Treasurer, Building and Construction Trades Department, AFL-CIO, Washington, D.C.

CHARLES P. GRAVES, College of Architecture, University of Kentucky, Lexington, Kentucky

CALVIN S. HAMILTON, Director of Planning, City of Los Angeles, Los Angeles, California

WALTER R. HIBBARD, JR., Vice President, Technical Services, Owens-Corning Fiberglas Corporation, Toledo, Ohio

MATT M. JETTON, President, Sunstate Builders, Inc., Tampa, Florida

RUDARD A. JONES, AIA, Director and Research Professor of Architecture, Small Homes Council–Building Research Council, University of Illinois at Urbana, Champaign, Illinois

W. E. KEMP, Director, Technical Planning, Development Department, Koppers Company, Inc., Pittsburgh, Pennsylvania

WILLIAM G. KIRKLAND, Vice President, American Iron and Steel Institute, Washington, D.C.

RICHARD G. LUGAR, Mayor, City of Indianapolis, Indianapolis, Indiana

OTIS M. MADER, President, Alcoa Building Industries, Pittsburgh, Pennsylvania

SHERMAN J. MAISEL, Fellow, Center for Advanced Study in the Behavioral Sciences, Stanford, California

D. QUINN MILLS, Alfred P. Sloan School of Management, Massachusetts Institute of Technology, Cambridge, Massachusetts

THOMAS F. MURPHY, President, Bricklayers, Masons, and Plasterers International Union of America, Washington, D.C.

AUSTIN J. PADDOCK, President and Chief Executive Officer and Chairman of the Board, Blount, Inc., Montgomery, Alabama

JOSEPH A. RORICK, Director of Design and Engineering, Real Estate and Construction Division, IBM Corporation, White Plains, New York

CHARLES E. SCHAFFNER, Vice President, Syska and Hennessy, Inc., New York, New York

ALFRED W. TEICHMEIER, President, Diversified Products Division, Champion International, New York, New York

EMIL TESSIN, II, Azimuth Equities, Inc., Newport Beach, California

JOHN F. C. TURNER, Department of Urban Studies and Planning, Massachusetts Institute of Technology, Cambridge Massachusetts

ROBERT C. WEAVER, Professor of Economics, The City University of New York, New York, New York

BEVERLY A. WILLIS, AIA, Willis and Associates, San Francisco, California

JOSEPH H. ZETTEL, Vice President, Johns-Manville Products Corporation, Denver, Colorado

LIAISON MEMBERS

ROBERT E. ISAACS, Director, Office of Program Management, Mail Processing, Research and Engineering Department, Washington, D.C.

WILLIAM L. McGRATH, Carlyle Air Conditioning Company, Ltd., London, England

ARTHUR F. SAMPSON, Acting Administrator, General Services Administration, Washington, D.C.

EDWARD J. SHERIDAN, Deputy Assistant Secretary of Defense (Installations and Housing), The Pentagon, Washington, D.C.

FREDERICK K. WILLENBROCK, Director, Institute of Applied Technology, National Bureau of Standards, Washington, D.C.

MEMBERS EX OFFICIO

JOHN P. GNAEDINGER, President, Soil Testing Services, Inc., Northbrook, Illinois

ROBINSON NEWCOMB, Consulting Economist, Vienna, Virginia

J. DONALD ROLLINS, Executive Vice President (International), U.S. Steel Corporation, Pittsburgh, Pennsylvania

Foreword

Shelter, a basic human need, is chronically and critically in short supply in many developing areas of the world. Of all the elements of shelter, the roof is perhaps the most important in providing protection from harsh environmental conditions, and it often meets cultural needs as well. Emphasis on roofing needs, and thus research on improved roofing technology, is fully justified at this time and, indeed, an essential first step in improving housing technology.

Historically, people solved their shelter problems by using native materials. They considered traditional roofs of local materials adequate until they came in contact with distant places and learned of different techniques and materials. In efforts to improve roofing, they imported new materials and new technology, sometimes combining the imports with local or readily available substances. When imports required a departure from tradition, many communities rejected innovations because of the accompanying changes in art forms, lifestyles, and technology. In other instances, where new materials and technology have been accepted, they have proved too costly to meet the demand, or they have increased hazard to life and health, even though they represent an improvement in the provision of shelter per se. In many developing areas, climatic conditions alone decrease the durability of even the best roofing materials used in more industrialized, temperate-zone countries. The task of achieving substantive improvements in roofing is formidable.

This report represents the voluntary efforts of an Advisory Committee of the Building Research Advisory Board appointed especially to consider feasible and practical new-technology solutions to roofing problems in developing

countries. The committee included highly qualified individuals who, at the request of the National Academy of Sciences-National Research Council, gave freely of their time and expertise in behalf of advancing building technology in developing countries.

The Building Research Advisory Board appreciates the contributions committee members have made and takes this opportunity to acknowledge their effort. In addition, the board extends its appreciation to all others who assisted the committee, particularly William Reps, National Bureau of Standards; Frederick Krimgold, Doctoral Candidate, Stockholm, Sweden; Henry Sjaardama, CARE, Inc.; Robert J. Cowan, CARE, Inc.; W. Ludwig Ingram, Central American Research Institute for Industry (ICAITI), Guatemala; David DeSelm, U.S. Department of Housing and Urban Development; and Mario A. Piche Alfaro, U.N. Centre for Housing, Building and Planning.

Joseph H. Newman, *Chairman*

I. Introduction

THE ROOFING PROBLEM

The full impact and implication of the roofing problem currently experienced by developing countries cannot be realized without some familiarity with the overall housing problem. More than 80 developing countries suffer from an acute housing shortage, principally because of the ever-increasing need for new housing created by expanding populations and the periodic large-scale loss of housing from natural disasters. Each country must overcome serious social, economic, and technical obstacles if the most basic needs and demands for shelter are to be satisfied. For most developing countries, the housing deficit is the most complex problem and one that will become more serious as population growth continues.

The housing deficit is further compounded by the fact that population growth, and the demand for new and improved housing, is greatest in areas where social and technological impediments are the most difficult to address and personal income is lowest. Already enormous financial needs are continually aggravated by extremely limited purchasing power and the absence of a credit system. Much of the population has an income so low that it cannot afford even the most modest housing.

Needs, and thus the basic factors in reaching any solution to the overall housing problem, vary considerably according to location. Designs for new housing in urban areas should take into account the increased hazards to life and health created by population density; yet, doing so will increase costs.

At present the formation of new households and the migration of rural households, or heads of households, to places of employment frequently lead to uncontrolled new, and often population-dense construction surrounding major cities (e.g., Calcutta, Rio de Janeiro, Ibadan). Most such urban housing—and often rural housing as well—is uncontrolled, poorly constructed of scavenged materials, unsanitary, unsafe, and short-lived. Disaster-prone areas need housing that is both safe and capable of rapid and high-volume production. In planning housing for developing countries in tropical and subtropical regions, continuous attention must be given to the ever-present problems of the environment's deteriorating effects on materials.

The most serious obstacle to low-cost housing in the developing countires, regardless of setting or sophistication, is the lack of a low-cost roofing material that will provide satisfactory performance for a reasonable time under many adverse conditions. An essential component of a dwelling, the roof is critical to shelter, thermal comfort, privacy, and, in some localities, the satisfaction of other needs—for a status symbol, a refuge from floodwaters, a sleeping area, a water-collection system, a storage area, a food- and clothes-drying area.[1,2] In many developing countries roofing alone represents more than 50 percent of the total construction cost of a low-cost house.

Usually, roofing for low-cost housing in developing countries is not the product of any organized building industry or process. Instead, it is constructed with local self-help labor using rudimentary processes and materials. Most roofs made of low-cost, indigenous materials such as thatch or unfired clay lack durability and can be hazardous to health and safety. The materials often are subject to moisture-induced decay; they harbor vermin and insects and are particularly dangerous during fires, windstorms, earthquakes, and other disasters. To provide more permanent roof coverings, many developing countries expend scarce foreign exchange to import corrugated galvanized iron (CGI) and other metal roof-covering materials from industrialized countries in the temperate zone. These materials are often too costly for much of the population and, where they are used, do not solve the roofing problem. Metal products do offer the advantages of being relatively long lasting, salvageable after a disaster, self-supporting over short spans, easily maintainable, and simple to install. In hot climates, however, the heat absorbed by metal roofs converts homes into ovens. Where exposed to saltwater spray, ferrous metals corrode quickly.

OBJECTIVES OF THIS REPORT

In view of the magnitude and complexity of the roofing problem in developing countries, the Agency for International Development (AID) requested

the Board on Science and Technology for International Development (BOSTID) of the National Academy of Sciences to review the practicality of a major research effort to develop new solutions to roofing problems in developing countries.

BOSTID invited the Academy's Building Research Advisory Board (BRAB) to conduct the review. In turn, BRAB appointed a special advisory committee of individuals with special knowledge of the technical, social, economic, and manufacturing aspects of roofing in developing countries. Two members of the committee were from developing countries; each directs his nation's housing research efforts.

The committee reviewed past and current research and development (R & D) activities directed at solving particular roofing problems of developing countries, as well as more general roofing R & D in other countries throughout the world. The committee found that most such R & D deals with the problems associated with roofing materials now in common use, or aims at improving a specific material or product, or seeks better uses of materials or products already available but used for purposes other than roofing. The committee further determined that although none of the current R & D activities reviewed demonstrates immediate solutions to the roofing problem, limited work is being, and has been, conducted on materials currently used for roofing (such as thatch, CGI, aluminum, and clay) and an extensive literature exists.[1] The committee decided, therefore, to explore the feasibility of developing new low-cost products and processes with potential for providing roofing materials that offer better performance than those most commonly used today.

This report presents the committee's conclusions and recommendations concerning areas of research and kinds of materials indicating significant potential for the development of new roofing technologies that could provide early solution to the particular problems of developing countries. Ten appendices address various technical aspects of potential new roofing technologies.

II. Conclusions

Conditions in the developing world vary greatly among countries, and even within countries, making it virtually impossible for the committee to address all problems associated with specific locations. During the conduct of its study, however, the committee did consider such regional conditions as the economic, social, and political acceptability of various materials, the availability (or lack) of credit facilities, climate, biological agents, and transportation problems.

On the basis of its study and its own knowledge, the committee arrived at the following conclusions:

1. The introduction of high-performance roofing systems that are low in cost and capable of adaptation to satisfy local social-acceptance requirements, could, of itself, significantly accelerate production of more and better housing. Furthermore, research directed toward development of fresh approaches to roofing problems in developing countries is likely to be productive at this time; in polymer science, in innovative applications of cement and asphalt, and in the improved use of indigenous vegetable, animal, and mineral products, the committee members found sufficient unrealized potential to convince them that, given adequate research funding, new solutions can be found.

2. The roofing problems of developing countries are such that proposed solutions must be conceived, analyzed, and evaluated in terms of a system comprised of the following three principal elements, singly or in combination:

- the supporting structure (e.g., trusses, beams);
- the roofing substrate (e.g., concrete slabs, wood boarding); and
- the roof covering (e.g., tiles, built-up roofing materials, waterproof coatings).

3. For each of these three elements, consideration must be given to

- Availability of materials in or close to the locale in which they are proposed for use. Proposed roofing systems should maximize the use of materials either obtainable from, or manufactured in, the country for which the systems are intended. Wherever possible, the systems should make use of materials that can be obtained from, or produced near, the point of use, to decrease dependance on local transportation systems. Furthermore, materials requiring local material resources should be selected only after investigation determines that those resources are available. (For example, high-quality concrete requires a supply of clean, fresh water, which may not be available.)
- Availability of labor required for production, transportation, and erection or construction. Domestic production would generate employment and stimulate the growth of supporting industries and services, as well as provide opportunity for improving worker skills.
- Skills and skill levels required for production, transportation, and erection or construction. Most developing countries have an abundant supply of unskilled labor, especially in urban areas. Insofar as possible, roof systems should be of simple design and easy to install, to provide employment and skill-training opportunities for local labor.
- Potential hazards to the health and safety of housing occupants and the community. Health and safety are, of course, of paramount importance. If synthetic materials, particularly plastics, are to be utilized, the flammability, smoke generation, and toxic characteristics should be given special attention. For locations known to be subject to earthquakes, floods, and high winds, the roofing system should be designed and constructed both to provide occupant protection against such hazards and to ensure that even if structural failure occurs, the threat to the community from falling or flying debris will be minimized.
- First cost, durability, maintenance costs, and the effect of each on the total roofing system. A durable but inexpensive roof covering that requires a costly or complex structure for support can lead to a total roofing system that is so uneconomical that it is completely unacceptable. The durability of the structural support and the roof substrate material should be considered, as well as that of the roof covering. Each should employ materials that can be maintained easily by the occupants or by local labor.
- Environmental conditions of the locale in which the material is proposed for use, particularly if it will be subjected to tropical and subtropical

climates. Special attention should be given to the possibility of degradation by ultraviolet light, moisture, biological agents, and damage by rain, wind, and earth movement. The roof covering or substrate should have a thermal insulating value sufficient to protect the interior from the heat of the sun during the day and, if enclosed or enclosable, to preserve interior-produced heat during the night. In hot climates, the roofing system should be designed and oriented to reduce the effect of the sun's heat and to take maximum advantage of prevailing breezes.

4. Searches for low-cost materials or systems embodying the above-mentioned characteristics should include composites containing a reinforcement, a filler, and a coating, all of which are held together by a "binder."* Research into composite materials could lead to the development of roofing materials capable of utilizing a vast array of indigenous products. (For a discussion of some composites and related ingredients, see the appendices.)

5. Insofar as possible, local products should be utilized for each component of a composite. For example, vegetable fibers, rock wool, glass fiber, and wire mesh ought to be considered for reinforcement; soil, waste glass, rock, and sawdust ought to be considered for fillers; and paint, whitewash, and sand sprinklings ought to be considered for coatings. (See appendix J for a more extensive list of possible component materials.)

6. Although potential reinforcement, filler, and coating materials are available in each of the developing countries, suitable binders to hold them together generally are not. If suitable binders can be developed and simple, low-cost methods can be devised to use them in the manufacture of composites, such composites might well provide the versatility required to meet local needs in widely differing developing regions.

7. To the fullest extent possible, R & D in roofing technology ought to be conducted within the developing countries, even if the cooperation of public, private, or academic institutions of more developed countries must be sought. Research and design specialists living in developing countries will be more cognizant of available resources and the design requirements peculiar to their specific localities. Furthermore, new roofing technologies generated by a developing country will probably be more easily diffused among, and accepted by, the local population.

*In some composite materials one component may serve more than one function; in others, one function may be unnecessary. For example, a separate coating to protect the surface or a filler to give bulk and weight may not be required.

III. Recommendations

During its investigation, the committee identified a wide variety of materials that researchers could consider in a search for new roofing systems for developing countries (see appendix J). Since developing countries differ so widely in their needs, climates, and available materials and resources, each must determine independently which avenues of research are most promising. The committee believes, however, that an organized, systematic approach to the establishment and direction of R & D programs within the developing countries could lead to early results of immediate use for most, if not all, countries. Thus, the committee offers the following recommendations:*

1. AN INTERNATIONAL ADVISORY COMMITTEE

A standing advisory committee should be established under appropriate international auspices. Its efforts should be directed specifically to accelerate, enlarge, and consolidate the dispersed low-cost roofing research programs for developing countries that now exist. The committee should give emphasis to regional rather than global approaches.

*This report was completed before the recent rise in crude oil prices. Substantially increased costs of petroleum derivatives will adversely affect the competitiveness of polymeric binders and foamed plastics (recommendations 2 and 3) and will increase the attractiveness of the nonpetroleum-based technologies discussed in recommendations 4–10.

Typical of the needs such a committee could address is a systematic inventory of roofing materials and the design and construction practices currently utilized in developing countries, as well as roofing problems now being studied by those countries and other research organizations. Such an inventory would make possible the identification of research gaps and areas calling for more attention.

Most committee members should be housing experts from developing regions; others should be drawn from the most appropriate research and academic facilities worldwide and from technical assistance organizations that have substantial interest in, and considerable resources committed to, housing in developing countries (such as AID; World Bank; United Nations Development Programme; United Nations Centre for Housing, Building and Planning; Inter-American Development Bank; Organization of American States; CARE).

2. POLYMERIC BINDERS

Roof-covering research, development, and demonstration programs should be directed toward the use of existing, commercially available unsaturated polyester and related polymers for binding combinations of indigenous materials (such as vegetable fibers, earths, and fabrics) of selected developing countries.

Such effort could be productive now because the technology of fabricating building products using thermosetting (e.g., unsaturated polyesters) and thermoplastic resins and related polymers in combination with other materials is highly developed and well documented (see appendix A). If such products are compatible and blend with locally available raw materials, they could be made in almost limitless shapes and sizes to meet designs required by a variety of customs and traditions. The committee believes that a concerted program of pilot-level development and testing could produce composite materials suitable for low-cost roofing systems in most developing countries.

The major challenge will be to develop inexpensive composites that will resist deleterious elements such as moisture, ultraviolet light, insects, and fungi. Special emphasis should be placed on identifying potential hazards associated with products utilizing plastic materials. For example, if open-fire cooking is done indoors, certain plastic roofing elements may ignite and produce injurious smoke or toxic gases. Polymers can be treated by fairly simple techniques to perform well when directly exposed to fire. But, to date, applications of such treated polymers have been relatively expensive.

If materials that perform adequately can be developed at reasonable cost, the manufacturing technology and application probably could be transferred

throughout developing countries with little difficulty; the simplicity of producing synthetic-resin roofing materials would permit easy diffusion of the technology and ready commercialization by small-scale entrepreneurs. The finished building products are likely to be economically competitive with, or have a price advantage over, CGI. The materials also may be used for applications other than roofing.

The costs of manufacturing the roofing composite could be very small. The system would be versatile and lend itself to labor-intensive production.

In their raw state, basic resins and polymers are stable and can be stored for some time, but, to maintain their specified characteristics, they must be kept in a cool, shaded location. Since they are concentrated, they require little shipping and storage space and have little intrinsic value until processed into a building material. If the basic resins and polymers are not available in developing countries, they would have to be imported but would probably represent only a minor portion of the cost of the finished roof. No significant logistical problems need to be overcome in importing bulk resins and polymers—abundant supplies and numerous manufacturers exist, and end-point handling, storage, and transportation are not difficult.

Field-research efforts on this type of application should include a cost-benefit analysis of imported resins as opposed to alternatives such as imported CGI.

3. FOAMED-PLASTICS PROCESSING

A pilot project should be undertaken to process foamed plastics suitable for roof-covering materials and to develop a mobile, small-scale, foaming-equipment system that developing countries could produce economically.

Foamed plastics—lightweight cellular substances produced by introducing gas bubbles into plastic compounds during manufacture—offer significant potential as versatile, lightweight roofing materials with high insulating values that could be produced on site in a variety of shapes and sizes (see appendix B). To date, the use of foamed plastics has been severely limited by the lack of simple, low-cost, reliable foaming equipment capable of producing a high-quality, uniform product.

The customary foamed-plastic processing equipment generates the foam chemically and then sprays the stabilized, frothy mass of fine bubbles into the desired position. In the past, the processing equipment used in field demonstration projects in developing countries was quite complex and sensitive and required costly maintenance; recent advances in equipment design, however, have eliminated many of the problems experienced earlier. Therefore, it would seem most appropriate and timely to incorporate these advances

in the development of a mobile, small-scale foaming system that could be mass-produced by the developing countries. Such a system, coupled with a demonstration that foamed plastics can be used in conjunction with indigenous reinforcing fillers and coatings as roof-covering and substrate materials, could lead to the formation of profitable local business enterprises that would produce both the equipment and a variety of foamed-plastic products.

The recommended pilot project should be organized clearly as an experiment to assess and document the performance of the equipment, as well as the economics, consumer acceptance, use, longevity, and durability of the prototype roofs produced. The project might well be conducted as a cooperative effort between U.S. and developing-country enterprises, with participation of academic institutions, building-oriented professional and trade organizations, and technical assistance agencies in the housing field.

It should be noted that recently the U.S. Federal Trade Commission charged that polyurethane and polystyrene foams subjected to fire can be hazardous to life and health in certain housing applications. This fact is well known by building technologists; however, foams with reported low flame-spread and smoke development are available today and its is likely that further improvements will appear in the near future. Nonetheless, those researchers developing foamed plastics for roofing materials in developing countries should be cognizant of the potential fire-related hazards and keep abreast of technical developments in this area.

4. SULFUR

Sulfur should be given serious consideration as a material for binding mixtures of other indigenous materials, as a valuable coating and joint-grouting material, and as a material from which small-size roofing products, such as tiles, can be made.

Although sulfur has not been widely used as a building material, its full potential as a binder for use in low-cost roofing for developing countries (see appendix C) should be explored. Only in the last decade has the use of this material for construction purposes been subjected to comprehensive scientific investigation. Its use in developing countries is particularly worth consideration because many have abundant supplies of sulfur as a result of volcanic activity and as a by-product of oil refining. Sulfur also could prove to be an inexpensive import item for countries lacking an indigenous supply.

Previous research and testing have been directed primarily toward the use of sulfur in sulfur-concrete and as a surface bonding agent. Elemental sulfur is a bonding agent with unique properties: It becomes molten at 240 °F, only slightly higher than the boiling point of water; it is insoluble in water and

demonstrates qualities of water impermeability; it is odorless, nontoxic in normal use, and a poor conductor of heat; it has an indefinite storage life; and it can be reprocessed. All these features indicate excellent potential for use in developing countries as a roofing material.

Elemental sulfur is particularly suitable for labor-intensive construction methods, but does have certain limitations: It is highly flammable, and it must be converted to a liquid state before aggregates or fillers can be added. Product developers and users must also be aware of the possible release of sulfuric acid in the presence of moisture and the potentially harmful effects of ingestion. Advantages seem to outweigh the disadvantages, however, and a concerted R & D effort is warranted at this time.

5. CARBONIZED PLANT MATERIALS

A laboratory-research and field-demonstration program should be conducted on the transformation into low-cost, lightweight roofing sheets of carbonized and expanded, nonfood, high-starch plant products that have been combined with unsaturated polyester resins and related polymers (see appendix G). Research should include local field surveys to identify types, quantities, and availability within the developing countries of plant products suitable for this purpose.

6. AGRICULTURAL AND WOOD WASTES

An intensive program should be initiated to develop economical processes for manufacturing resins from native agricultural products (e.g., natural vegetation, bagasse) for use primarily as binders.

As noted in appendix G,[1] the lignin and furfural in vegetation can be used as *in situ* binders if heat and pressure are applied. This technology is well known in industrialized nations; it is probable that simplified processing methods would permit developing countries to produce an abundant supply of satisfactory building panels.

7. WASTES FROM PRIMARY INDUSTRIES

Wastes such as fly ash and blast-furnace slag from the steel industry have properties that make them suitable as cementitious binders (see appendix E) and should be investigated. These wastes could prove of particular value in countries lacking adequate limestone and portland cement resources.

Red mud, a copious by-product from bauxite refining that gluts many developing countries, also merits serious consideration, as do metallic wastes from the production of iron and steel. Disposal of these and similar waste products is an ever-increasing worldwide burden to heavy industry; their conversion to useful products would serve a two-fold purpose. Research in such alternative uses may be so attractive to the affected industries that they might be induced to contribute funds or materials.

8. CONCRETE

An analytical and laboratory testing program should be undertaken to develop more appropriate and economical reinforced concrete products. (See appendix H on ferrocement.) The research effort should focus on the use of reinforcing materials such as wire mesh, locally available chopped wire, glass fibers, rock wool, and various vegetable products such as bamboo,[2] bark, and wood fiber (wood-fiber concrete is known as "wood wool" in some parts of the world[3]). Consideration also should be given to substitutes for portland cement, some of which are suggested in appendix E.

9. CLAY-BASED MATERIALS

A research program should be undertaken to develop methods for improving the general performance and range of applications of clay-based roofing materials. (See appendix I.)

10. FIBER PRODUCTS

The suitability and effectiveness of waste raw materials from textile and other fiber industries (based on such fibers as jute, sisal, hemp, kenaf, and cotton) common in developing countries as a blend in a composite material for roofing components should be explored.

In summary, there are numerous promising avenues of exploration, and it is the opinion of the advisory committee that full advantage should be taken of them at this time.

Appendix A. Plastics

By chemical definiton, plastics (also known as polymers) are synthetic, chainlike molecules of high molecular weight that are the end result of the chemical binding of large numbers of smaller molecules known as monomers. Today there are approximately 40 families of plastics.

Each plastic has a well-defined combination of properties, processing requirements, and economics that make it uniquely applicable in certain situations and unusable in others.

In developing countries, plastic resins containing monomers could, in principle, be combined with locally available reinforcement and fillers by local labor using low-cost equipment to form roofing sheets that could substitute for currently used corrugated metal sheets. The widespread availability of the chemicals, the relative ease of training local labor to make such roofing, and the low cost of equipment all strongly suggest that a project should be initiated to develop such roofing.

A development program for using plastic resins in this manner would have these advantages:

- A local industry might result, to manufacture roofing materials.
- The use of indigenous materials and local labor would contribute to the economic growth of less developed nations.

Contributed by Trayon Onett, Marketing Manager, Research Department, Koppers Company, Inc., Monroeville, Pennsylvania.

- The reinforced plastic sheets would be lightweight, weather resistant, translucent, verminproof, corrosion resistant, and potentially low cost.
- The use of this type of material would relate roofing solutions to the general housing problems of developing countries.
- The use of indigenous materials would help overcome the problem of local acceptance of shapes, styles, and aesthetics usually associated with the introduction of new materials. Though a new material is used, the house could be constructed in a traditional architectural form.
- The development program would establish the extent of training necessary to use existing talent and skills.
- Walls and floors could later be made from different proportions of the same ingredients.

To utilize these advantages and implement such a development program, it is recommended that

1. A complete program for evaluating indigenous reinforcing, fillers, various resins, additives, and stabilizers be initiated. The results of this program could be incorporated into pilot development plans for larger-scale construction, testing, and field evaluation.
2. As the physical testing and evaluation program are initiated, a market acceptance and economic feasibility program be started in a developing country.

SELECTION OF A PLASTIC

With over 40 families of plastics available and hundreds of variables possible within each, determining the balance of properties required in the end use becomes most important. Today, polymers can be tailored to produce bulk fiber, foam, film, coating, and adhesive plastics that may be hard or soft, rigid or flexible, rubbery or leathery, and porous or nonporous.

Some of the physical considerations that must be considered are the end-product requirements for the following characteristics:

Stiffness or flexibility
Temperature range
Tensile, flexural, and impact strengths
Intensity, frequency, and duration of loads
Color retention under environmental conditions
Electrical properties
Moisture resistance
Chemical resistances

Weather and sunlight resistance
Odor and taste
Production requirements (quantity and speed)
Material costs

The ratings of physical requirements will be assigned ranges (e.g., tensile strength: 4,218,600 kg/m^2 or 6,000 psi, essential; above 5,624,800 kg/m^2 or 8,000 psi, desirable; above 8,437,200 kg/m^2 or 12,000 psi, unimportant). Choosing the best plastic for a specific job then becomes a matter of finding the one material that best combines the necessary and desirable properties per unit cost.

Plastics are differentiated as either thermoplastic or thermosetting. Thermoplastic resins require heat to form plastics, and the final plastic can be remolded a number of times without loss of properties simply by applying more heat. Thermoplastic scrap can be reclaimed and reprocessed without difficulty. Chemically, the plastics they produce are linear molecular chains that fuse and solidify without serious chain breakage and without much cross-linking. Polyethylene, polystyrene, polyvinyl chloride, cellulosics, and nylon are examples of thermoplastic resins.

A thermosetting resin forms a plastic with a permanent shape that cannot be altered reversibly when heated. The final plastic after setting is a cross-linked, intractable, nonflowing material. Applying additional or higher heat only destroys it. Thermoset scrap cannot be reprocessed and can only be reused as filler material. Typical plastics in this family are polyesters, phenolics, and ureas.

Certain thermosetting resins require no heat and little or no pressure to form their final shape. They achieve cure by reacting with other chemicals at room temperature to create their tightly cross-linked chain structures. These reactions occur in relatively short times, and the final cure and set are permanent. Among these are some specific polyesters, epoxies, silicones, and polyurethanes.

THERMOPLASTIC RESINS

The descriptions of thermoplastics presented below will serve as a quick introduction to this branch of the plastics industry.

ACRYLONITRILE-BUTADIENE-SYTRENE (ABS)

Very tough; has an unusual combination of a high rigidity and impact strength; readily accepts decorating or plating; possesses excellent embossing properties; has fair chemical resistance, very low water absorption, good di-

mensional stability, and high abrasion resistance; formulation can be varied to obtain different combinations of flexibility, heat resistance, and toughness.

ACETAL

An engineering plastic with very high tensile strength, stiffness, and exceptional dimensional stability; has high chemical resistance, high abrasion resistance, low moisture absorption, excellent resistance to creep under load, and low tendency to stress cracking; is nontracking electrically; has low coefficient of friction and superior retention of physical properties if immersed in hot water. Two types are available—homopolymeric acetals that have higher strengths, and copolymeric ones that are easier to process.

ACRYLICS

Widely used for their high optical clarity and brilliant transparent colors; best of the transparent plastics in resistance to outdoor weathering; excellent electrical strengths; hard, glossy surface; fair chemical resistance. Available for fabrication as acrylic sheets or standard and high-impact molding powders.

CELLULOSICS

Among the toughest of plastics; five basic cellulose families—nitrate, acetate, propionate, butyrate, and ethyl celluloses. Nitrate, the toughest, is highly inflammable and explosive and embrittles with age. Acetate is easier to process and not explosive but has poor solvent resistance and embrittles with age. Propionate and butyrate are chemical and weather resistant.

FLUOROPLASTICS

Four general types—polytetrafluoroethylene (TFE), chlorotrifluoroethylene (CTFE), fluorinated ethylene (FEP), and polyvinylidene fluoride (PVF_2). TFE is nonburning and has very high heat and chemical resistance (up to 550 °F), excellent resistance to heat aging, the lowest coefficient of riction of any plastic, very high dimensional stability, and zero moisture absorption, but is very difficult to process. CTFE has most of the outstanding properties of TFE but is somewhat easier to mold. FEP is very easy to mold but is the most expensive of the fluoroplastics. PVF_2 has heat resistance to 300 °F, is the easiest to mold, and has higher tensile strength* and lower cold flow† than the other fluoroplastics.

**Tensile strength*: the pulling stress in pounds per square inch required to break a given specimen.

†*Cold flow*: the tendency to change dimensionally with time under load (e.g., creep at room temperature.

IONOMER

A generic name for polymers in which ionized carboxyl groups create ionic cross-links in the intermolecular structure. They offer excellent toughness and high optical clarity, superior resistance to oils, greases, and solvents, and high abrasion resistance. Their high melt strength permits very deep draws in thermoforming, and they are very resistant to stress cracking. Films have outstanding flexibility and are hard to tear but have easy tear propagation.

METHYL PENTENES

Offer excellent transparency; short heat resistance to 430 °F, good chemical resistance, and low water absorption. Have the lowest specific gravity (0.083) of any commercial plastic, superior electrical strengths at high temperatures, sharp melting point at 464 °F, and poor resistance to outdoor weathering. Are easier to process than most high-heat plastics.

NYLONS (POLYAMIDES)

Are self-extinguishing if ignited and offer outstanding toughness and wear resistance, a very low coefficient of friction, excellent chemical resistance, high electrical strengths, poor dimensional stability due to hygroscopy* and cold flow.

PHENOXIES

Offer outstanding chemical resistance except for organic solvents; are tough, hard, and ductile; show low shrinkage during molding. Compared to other thermoplastics, they have the lowest creep resistance, permeability to gases, and coefficient of thermal expansion.

POLYALLOMERS

Similar to polyethylene and polypropylene, but with high abrasion resistance, broader processing conditions, and better stress/crack resistance. Offer excellent embossing properties, low specific gravity, and short molding cycles.

POLYCARBONATES

Rigid, transparent, tough engineering thermoplastics offering excellent outdoor dimensional stability, very low creep under load, fair chemical resistance,

**Hygroscopy*: the tendency to absorb moisture.

and excellent impact resistance. Are self-extinguishing if ignited, physiologically inert, and ductile enough to yield rather than shatter under load.

POLYETHYLENE

An excellent combination of electrical and physical strength; lightweight, easy to process, and low cost; offers good toughness, flexibility, and chemical resistance; easily heat sealed, but heat resistance limited to 180 °F; has poor stress/crack resistance and is difficult to hold to tolerances in molding. Available as low-, medium-, and high-density polyethylene. The stiffness and physical strengths increase toward the higher density.

POLYAMIDES

Maintain heat resistance to 500 °F continuously and up to 900 °F for short periods; offer very low coefficient of expansion, outstanding resistance to heat aging, high impact strengths, and excellent wear resistance; are the most difficult to process so they must be sintered or solution coated; are very expensive.

PHENYLENE OXIDE

Engineering plastic, very tough over a temperature range of 275 °F to 375 °F; offers superior dimensional stability, low moisture absorption; highest resistance to creep under load, and excellent chemical resistance. Modifications available at lower cost but with lower heat resistance.

POLYPROPYLENE

Offers excellent resistance to stress or flex cracking, very low specific gravity, excellent impact strength, good chemical resistance; floats on water; forms films and fibers having superior strength, optical qualities, grease resistance, and moisture-barrier properties.

POLYSTYRENE

General-purpose grade very rigid; shows low moisture absorption, low shrinkage during molding, high optical clarity, and poor outdoor stability; many solvents attack polystyrene; easy to process. Many modifications of polystyrene are possible (e.g., adding butadiene for impact resistance, making copolymers of styrene-acrylonitrile for high strengths, or adding blowing agents for foamed parts).

POLYSULFONE

An engineering plastic showing good transparency, high mechanical strengths, high heat resistance, superior electrical strengths at high temperatures, unusual resistance to strong mineral acids and alkalis, and superior retention of properties on heat aging.

POLYVINYL CHLORIDES (PVC)

Of two basic types—rigid and flexible; tough, hard, and difficult to process; offer good outdoor stability, superior electrical properties, excellent resistance to moisture and chemicals; are self-extinguishing if ignited. Many copolymers and formulae variations are available for special applications.

THERMOSETTING RESINS

ALKYDS

Offer excellent dimensional stability, arc resistance, and high heat resistance; cure without creating volatile by-products; have very fast, low-pressure molding cycles making them easier to mold than most thermosetting resins; surfaces are hard, stiff, and tough. Various fillers and reinforcing fibers may be added to the resin to produce a wide variety of compounds, each offering a different combination of properties.

AMINOS (UREA AND MELAMINES)

Hard, rigid, and abrasion resistant; have excellent dimensional stability under load, good solvent resistance and chip resistance, and are self-extinguishing if ignited. Urea molds faster and costs less; melamine has higher surface hardness and heat resistance. Both are static-free and have excellent electrical properties. Fillers and reinforcing fibers are added for economy, better dimensional stability, and higher strengths.

DIALLYL PHTHALLATE (DAP)

Offers most exceptional dimensional stability of all the plastics as well as superior electrical properties and excellent heat and chemical resistance; surfaces are hard, tough, and have very low moisture absorption; is easy to mold at low pressures without forming volatile by-products; offers low postmolding shrinkage when glass-filled.

EPOXIES

Has outstanding physical and electrical properties and excellent adhesive properties; offers unusually low shrinkage during molding and superior dimensional stability under a wide variety of adverse environments; resins are normally liquids even without solvents or dilutants; some formulations can be cured without heat or pressure; many formulae variations.

PHENOLIC

Low-cost molding material with excellent combination of high physical strengths, high temperature resistance, good dimensional stability, and superior electrical properties; color limitation of black or brown; mineral, glass, and cotton flock materials commonly used as fillers.

POLYESTERS

Two types–saturated or unsaturated. Films and fibers are formed from the saturated polyesters; the unsaturated polyester resins, when reinforced, give products with excellent resistance to high temperatures and chemicals. Superior electrical properties and one of the most economic of all resin systems. Reinforced parts have high physical strengths and can be molded with little or no heat and pressure. Finished parts can be cast, molded, pultruded–or the opposite–laminated, foamed, or sprayed.

POLYURETHANE

Available as film, as well as rigid or flexible foam. Thermosetting types can be flexible and rigid, depending upon formulation. Good abrasion and wear resistance, superior impact resistance, and good electrical properties and chemical resistance. Thermoplastic forms are also available and are used to produce tough films and wear-resistant parts.

SILICONE

Offers excellent property retentions over wide temperature range, -100 to 500 °F; nonstick surface. Can be cured without heat or pressure; molding compounds can be rigid or flexible, depending on the type of silicone. Reinforcement with fillers yields extra strength. Silicone fluids are used to make mold releases, antifoaming agents, and water-repellent coatings. Physiologically inert.

REINFORCEMENT MATERIALS FOR PLASTICS

The addition of reinforcing materials to these families of resins can dramatically improve the strength, toughness, dimensional stability, and properties of electrical, thermal, and chemical resistance of the plastic formed from them. An initial screening of a resin and reinforcement system must include measurements of tensile strength, flexural modulus, impact resistance, heat deflection temperatures, flame retardance, and volumetric materials costs. The reinforcing material in greatest use in the United States is fiberglass, supplied as mat, cloth, roving (twisted strands of fiberglass), or continuous glass filaments. In addition, inert fillers of minerals, clays, and silicas are used to impart weather resistance and flame or chemical retardance. Final fabrication is accomplished by the addition of a catalyst for casting or ambient-temperature curing. If high production is required, the finished parts are usually pultruded, compression-die molded, bag molded, or vacuum formed. The addition of initiators, catalysts, fillers, and additives enables the processor to tailor a chemical system to the availability of materials, and the volumetric material costs.

Among the indigenous materials that can be used in reinforced manufacturing are asbestos fibers, fly ash, hemp, coconut fibers, jute, and groundnut shells (see also appendix J).

Appendix B. Foam Composites

The thermal characteristics and light weight of foamed materials suggest their potential for use in roofing if combined with reinforcement for increased structural strength.[1]

A major advantage of reinforced-foam roofs is that they incorporate in one unit the roof surface, insulation, supporting structure, and ceiling. The separate substructure and ceiling that must be used with other types of roofing materials is eliminated. As a result of the savings gained by eliminating the substructure, the cost of a bamboo-reinforced polyurethane composite roofing material, for example, is approximately one-third to one-half that of conventional materials. At present polyurethane is the most available of the matrix materials. Poor physical properties, high cost, or processing problems eliminate many other foams from further consideration for this application at this time.

Work on several different urethane foam formulations[2,3] indicates that rats, mice, and termites will not attack it. Rodents will chew and claw through only if it is placed between them and their regular food source. Work by Wessel[4] indicates that the urethanes have (on a scale of good, moderate, and poor) good resistance to attack by fungi and bacteria.

For use in residential structures, roofs must not pose a potential fire

Contributed by J. P. R. Falconer; adapted from a paper by D. J. Stubblefield, Falconer, and T. B. Moore, presented at the Third International Cellular Plastics Conference, Montreal, Canada, September 1972.

hazard to the occupants. This is a particularly important consideration when a foamed roof is used on a low-cost dwelling in a developing country since with no ceiling the foam is exposed to the interior where oil lamps, cooking fires, etc., could ignite it. Foams with low flame-spread and smoke-development ratings are available, and certain foams are nonburning. However, polyurethane and polystyrene formulations have recently come under question by the U.S. Federal Trade Commission as possibly representing a serious fire hazard. Furthermore, during combustion and even before ignition, some foamed materials have been shown to give off toxic fumes.

Aromatic polyurethanes and some other plastics undergo degradation when exposed to sunlight. This is particularly troublesome in tropical countries. Ultraviolet rays in sunlight produce free radicals that react with oxygen to produce a discolored, highly cross-linked, friable surface, which is sloughed off. This may be prevented by coating the foam with an elastomeric weather barrier.[5,6]

The long-term stability of a foam matrix in a hot, humid environment depends strongly on the molecular structure of the polymer. Work by Frisch et al.[7] indicates that polyurethane foam stability under hot, humid conditions is inversely related to the cross-link density. That is, foams with the lowest molecular weight between cross-links were the most stable. An extensive dis-

TABLE B-1. Cost of 500-sq ft Sprayed Bamboo/Foam Roof

Item	Cost (U.S.$)
Polyurethane foam	110
Bamboo	
700 culms @ 5¢	35
Mold cost	
200 2 × 10 ft panels/mold @ $40/mold	0

30% overhead and miscellaneous	98
	424
Total cost, $/sq ft	$ 0.85

*500 houses per year for 5 years, $15,000 for spray. A foam cost of $0.50/lb and a labor rate of $0.60/hr are assumed.

cussion of the effects of a foam's chemical structure on thermal degradation is presented by Tilley et al.[8]

The theory of fiber-reinforced foam composites is covered in a recent paper by Rinde.[9] This paper also discusses the preparation and testing of several different types of foam/fiber composites. Since the mode of failure usually associated with roofing materials is excessive deflection rather than fracture, the major mechanical property of interest in evaluating potential materials is the modulus of elasticity. Once the modulus is known, the roof thickness may be adjusted to limit the maximum midspan deflection under a given loading condition, and roof costs can be determined.

For developing countries, vegetable fibers are attractive to consider as potential reinforcement for foams. These fibers typically have a modulus of elasticity of 1×10^6 to 4×10^6 psi, and tensile strengths of 1×10^5 to 2×10^5 psi. As reinforcing they have the distinct advantage of being relatively inexpensive (compared with typical fiber reinforcements such as steel or fiberglass) and are available where the roof will be produced and used. Bamboo is a particularly attractive reinforcement, and an extensive program of research into bamboo-reinforced polyurethane foam sheets for developing-country roofing is now under way at Washington University.* Table B-1 lists a typical cost breakdown for such roofing.

MAKING THE FOAM

Since a multicomponent chemical system must be blended in accurate proportions in foam making, the equipment is complex, specialized, and expensive.

The development of foam-processing machinery has accelerated rapidly during the past 10 years and should continue as applications of foams increase. Recent developments, centered around the use of positive-displacement piston pumps vs. rotary-gear pumps, will reduce the requirement for temperature-conditioning equipment and the physical size of the machinery. Current work indicates that this will also simplify operational procedures considerably and give a higher degree of portability for on-site work.

Today, equipment manufacturers must also constantly upgrade, redesign, and innovate to keep pace with the improving urethane chemical systems. We can look forward to improved machinery performance with fewer maintenance problems, and perhaps most importantly, simpler operating pro-

*For further information, contact J. P. R. Falconer, Center for Development Technology, Washington University, St. Louis, Missouri, U.S.A.

cedures. All these factors will contribute to increased acceptance of roofing made of urethane foam systems.

Because of the complexity of the equipment, it is mandatory that operators be given intensive training. Those who are eventually assigned the responsibility of operating the equipment should possess a relatively high mechanical aptitude, and have previous experience in mechanical-equipment repair or operation. Some basic training to familiarize personnel with the chemical system may be desirable but from a functional standpoint is not required. Particular emphasis should be placed on developing troubleshooting ability and proper machine-maintenance procedures. A thorough study of the machinery manufacturer's manual should be required.

The foam can be made rapidly. For example, a 3-in. thick, 10-ft long, 10-in. wide roofing element may be foam filled in 20 seconds with a machine having a throughput rating of 30 lb/min. (This includes the time needed to assemble reinforcing in the molds.) It is feasible to produce one such roofing element per minute with equipment of this size.

SPRAY-IN-PLACE BAMBOO/FOAM COMPOSITES

Through the centuries, techniques have been developed for working with bamboo. Various types of woven mats, and poles wired together, are used for many purposes. In developing countries bamboo mats are often used as structural wall elements and as the base for roofing such as thatch.

Foam can be sprayed on both sides of a bamboo mat to provide thermal insulation and to give a unitized, sealed roof. The underside becomes the ceiling. After the exterior side is coated with a weather coating, it becomes durable and weather resistant.

This type of roof construction is ideally suited to self-help housing, since the homeowner can contribute a large part of the work. Also, with the spray-in-place technique, the builder has a great deal of architectural latitude in the final roof design, because almost any configuration can be set up before it is sprayed. This helps to eliminate a sometimes undesirable situation in which each house looks just like its neighbors.

Urethane spray machinery must, of course, be highly portable. Good design dictates a lightweight spray gun equipped with a suitable method for purging mixed material if an internal mixing chamber is used. The entire system is designed into an equipment package as small and lightweight as practical. The proportioning pumps should be adaptable to a variety of material volume ratios. Suitable provision for temperature control should be incorporated throughout the pumping system and through the flexible hose as-

semblies to the gun. Power, if electricity is unavailable in the field, may be provided by a gasoline- or diesel-powered generator.

Using a system commercially available in the United States, a two-man crew can spray from 7000 to 9000 sq ft per 8-hour day, including adequate time for start-up and shutdown procedures. Complex structures or forms and the need to use ascending-descending ladders, platforms, and scaffolds reduce this.

For large projects truck-mounted bulk tanks are desirable. Properly designed and built, mobile foam-spray units are efficient and economical.

To use the foam-spray approach, considerable training of spray personnel is required. Training programs have to develop a thorough understanding of all component parts of the spray-foam machine. This extends to a complete discussion of each component part, its purpose, and the possible causes for its failure. The trainee must be capable of disassembling and rebuilding the machinery, and he should be placed in situations in which he must diagnose a failure or improper function of the machine. His ability to recognize the problem, select the proper solution, and then carry out the repair properly is invaluable in the field.

Considerable attention must also be given to proper spray technique. To develop a smooth arm motion requires muscular coordination and extensive practice. In spraying a roof, arm motion must take place while the worker moves, particularly when he walks backward. Personnel experienced in using paint spray guns will find the arm motion quite similar. However, coupling this arm movement with walking backward on a roof deck usually must be thoroughly practiced before an acceptable finished surface can be consistently applied.

A complete spray-foam-operator training program, including printed manuals and visual aid training films, is now being developed in the United States.

Appendix C. Sulfur

Investigations of the past 10 years show that sulfur with plasticizers, aggregates, and fibers can be used in low-cost construction instead of, or in addition to, traditional materials.

Simple techniques and primitive equipment can be employed for melting and applying sulfur in small quantities (e.g., when it is used as a binder to cover joints in blocks, bricks, and slabs). However, to use large amounts of sulfur or for continuous production, practical techniques have yet to be developed.

Continued research is warranted and is justified by the following considerations:

- Sulfur is abundant in many parts of the developing world, particularly in volcanic regions. Oil refineries also produce sulfur in large quantities as a by-product.
- Sulfur can be used as a building material in low-cost construction, and its application requires relatively simple handicraft techniques.
- Sulfur is waterproof, adheres strongly to a wide range of materials, has no taste or smell, does not act on the skin, and is a poor heat and electricity conductor.
- Sulfur, when mixed with fibers, gains in tensile and flexural strength;

Contributed by A. Gonzalez-Gandolfi, Chief, Building Section, Centre for Housing, Building and Planning, United Nations, New York.

when mixed with natural and artificial aggregates, it produces a concrete of a quality acceptable for low-cost construction.

- Sulfur cures in minutes and can be cast in, and removed from, molds in a fraction of the time required for portland-cement concrete.
- Sulfur has high resistance to salt and acid solutions, and can be stored indefinitely.
- Sulfur can be reused.

However, sulfur has some drawbacks. One disadvantage—flammability—has prevented, until recently, its use as a building material. Today, a number of low-cost additives have been developed that reduce fire danger to levels meeting American Society for Testing and Materials (ASTM) performance requirements.[1] However, systems incorporating these have not yet been used widely enough to determine their cost-effectiveness.

Sulfur has been used in a minor way in housing for many years, for example, as grouting to fasten metal railings to masonry. Since about 1960, a systematic and wider investigation of this material has been undertaken. The Department of Chemistry and Chemical Engineering of the Southwest Research Institute, San Antonio, Texas, has built experimental buildings using sulfur and has investigated ways to spray sulfur and to make it more plastic and less flammable. The Texas institute has also developed methods to apply sulfur and to reinforce it with synthetic fibers.[1,2]

Further studies and experiments have been conducted in Guatemala,[3] Iraq, the United States (Columbia University),[4] Togo (sponsored by the United Nations), and Canada, by McGill University.[5]

SULFUR AS A COATING

If inexpensive sulfur spraying equipment can be developed, many building materials traditionally used for roofing (as well as some new ones) could be coated with sulfur to give increased strength and waterproofing. For example, even thatch roofs might be made more durable and waterproof.

A report of an exploratory study made by Columbia University under U.N. auspices states:

> A panel of reeds, a woven mat and a coarse cloth stretched on a wooden frame were impregnated and painted with sulfur. The resulting panels are quite stiff and completely waterproof even after cracks are induced by flexing the panels. Because of the low viscosity of the sulfur, the procedure is simplest with relatively dense fiber panels and tightly woven fabrics.
>
> Paper panels: the use of paper panels for low-cost, lightweight construction offering flexibility of form was considered in another project. The problem of waterproofing such panels can be solved with the use of sulfur coatings which adhered very well to

sample panels tested during the present study and also added to their strength in flexure.[4]

Some demonstrations in Guatemala proved that sulfur-sand and sulfur-pumice mixtures can be troweled onto wood-wool panels (wood fibers set in concrete). Further investigations have been recommended on roofing made of wood-wool panels with a waterproof coating of sulfur.[3] For coatings and some other uses, the brittleness of sulfur is a drawback but there are indications that this can be overcome.

Dr. B. R. Currell, Department of Chemistry, North London Polytechnic, reported in August 1971, that he had developed methods for plasticizing sulfur by adding unsaturated hydrocarbons to make it flexible.

SULFUR AS A BINDER

Sulfur-containing composite materials could provide strong, waterproof roofing membranes and high performance supporting structures. Experiments in the United States[1,2,4] and Guatemala[3] indicate the possibility of using sulfur as a binder with other materials, such as cement blocks and bricks, to make beams and slabs spanning 1.8288–2.4304 m (6–8 ft). Asbestos-cement is increased greatly in strength when impregnated with sulfur, and larger spans than those used in current asbestos-cement roofing practice might be possible.[5]

McGill University has produced very thin cast tiles. If they are cast in glass molds, a smooth 15 cm X 30 cm X 6 cm (6 X 12 X ¼ in.) rectangular roofing tiles are obtained. These could be used instead of clay or asbestos-cement tiles.

Slabs and tiles of different sizes, sulfur mixes, and finishes have also been made. A mix of sulfur, sand, and basalt aggregates, for example, was cast in a 60 cm^2 mold, 2 cm deep (24 X 24 X ¾ in.). The resulting slab can be used for flooring or roofing. Another demonstration was made using 50 percent of a local sulfur concentrate and 50 percent of pumice with which slabs 5 cm X 7 cm X 1 m (2 X 28 X 40 in.) were cast. Since the slabs are waterproof, they can be used as a roof plane without a roof cover on top, except for the joints. Techniques for grouting the joints should be investigated.[3]

Using sulfur in sulfur-concrete shells has been limited so far by difficulties in melting and pouring large quantities of sulfur. Sulfur-concrete composed of 70 percent sulfur, 25 percent sand, and 5 percent carbon black is reported to reach a tensile strength 47 kg/cm^2 (670 psi).[5] Demonstrations in Guatemala were successful with the following mix: 38.5 percent sulfur, 38.5 percent quartzite sand, and 23 percent pumice. Its compressive strength was 245 kg/cm^2 (3,500 psi).[3]

In 1969 a promising demonstration of sulfur's properties was made:

mineral resources indicates that future building material should, if possible, be produced from renewable resources such as vegetation. For example, in Europe mineral aggregates have become so scarce that roads now must be designed to eliminate the deep layers of gravel traditionally used as roadbeds.

To carbonize plant materials, kernels of common cereal grains—wheat, rice, corn—are expanded by applying heat and pressure, and the expanded kernels are converted to carbon by slow burning. The resulting product has a fine cellular structure containing entrapped air, which makes it an excellent lightweight insulator. The carbonization process renders the materials biologically inert, fire resistant (stable up to about 2000 °C or 3632 °F), and highly resistant to water and chemicals. Further development of this process will undoubtedly affect both the agricultural and construction industries.

To date, work in North America has centered on the use of edible cereal grains to produce the carbonized product; however, this can hardly be recommended for countries where food shortages exist. For these areas, research should focus initially on identifying locally available, nonedible grains or plant materials other than grains suitable for expansion and carbonization. Although it is likely that such indigenous materials exist or that exotic species of plants could be introduced and cultivated specifically for the purpose, there has been little reason to initiate such studies to date.

To develop roofing will require investigating suitable cements and binding agents for the carbonized particles. Some work has been done, again at Toronto, in binding the particles with low-penetration asphalt to produce a roofing board; asphalt, however, is a problem material in the tropics. Portland cement is an obvious alternative, which could produce lightweight insulating concrete for roof decks or precast roof slabs. But portland cement must sometimes be imported and, in such cases, raises the construction costs. Synthetic-resin binders may be viable in some areas, but might require pretreatment of the carbon particles.

The many variables and unknowns at this point of development suggest that the best approach is a comprehensive study in one or more tropical developing countries of the availability of suitable plant materials and an investigation of compatible binding agents to be developed specifically for use with those carbonized products that appear to hold the most potential for roofing in tropical environments.

The use of insulating building materials derived from plant products is an important concept for developing countries. They could be produced locally without draining foreign exchange reserve and could reduce the energy requirements for heating and cooling the buildings produced.

Appendix E. Hydraulic-Setting Cement Binders

This discussion deals with hydraulic-setting materials other than portland cement, which is well documented especially by the Portland Cement Association in the United States and similar organizations in other countries. The purpose here is to describe some other materials with hydraulic-setting properties that may be used as binders for roofing materials or, in some cases, as partial substitutes for portland cement.

Most materials described below offer binding properties deficient in some respects to those of portland cement. Accordingly, their usefulness as binders for roofing materials needs to be researched in terms of particular materials, applications, and locations.

It is hoped that some of these materials will offer a choice for developing a hydraulic-setting binder in areas where portland cement is available in limited quantities or not at all.

BACKGROUND AND POTENTIAL

The following six materials are starting sources for developing hydraulic-setting properties: (a) blast furnace slag, (b) fly ash, (c) limestone, (d) bauxite, (e) pozzolans, and (f) magnesia.[1]

Contributed by C. E. Bushnell, Manager, Building Products Research Unit, Armstrong Cork Company, Research and Development Center, Lancaster, Pennsylvania.

BLAST-FURNACE SLAG

Blast-furnace slag is formed in the process of iron manufacture from a combination of residues from the ore after separation of the iron, and from the limestone and ash from the coke used in the furnace. The slag rises to the surface and is removed from time to time. For use as a hydraulic-setting material, the slag is reduced in size by various means.

Finely ground blast-furnace slag alone does not produce a hydraulic set with water. Various materials must be added to "activate" the hydraulic-setting characteristic. Materials such as lime, portland cement, sodium and potassium hydroxides, and mixtures of salts giving high pH in solution are used.

Slag-based hydraulic-setting binders will probably offer lower strength than straight portland cement but otherwise should provide reasonable performance.

FLY ASH

Fly ash is a by-product of coal-burning power-generating plants. Created in abundance where such facilities operate, it is probably in oversupply since no single major use has been found for it. Probably not useful by itself as a hydraulic-setting binder material, fly ash does exhibit pozzolanic activity and is a practical extender for portland cement.

Certain fly-ash-containing concretes have demonstrated improved strength properties.

LIMESTONE

The greatest use of limestone is for portland cement manufacture; it is blended with other materials to provide hydraulic-setting properties. However, some impure limestone, usually argillaceous, possesses hydraulic-setting properties because its chemical composition is similar to that of portland cement. Lime calcined from limestone has been known to have binding properties for centuries. Hydraulic lime prepared by calcining impure carbonate materials, again argillaceous, also offers potential. Used for centuries in various regions, including South America and Asia, it has been replaced recently by portland cement and other newer materials.

With the exception of portland cement, materials derived from limestone would have less strength as binders and be somewhat water sensitive.

BAUXITE

Bauxite offers a starting point for developing aluminous cements, but it generally needs a source of limestone as well. To make hydraulic-setting materials, bauxite and limestone are fused at high temperatures and then the size of the resulting clinker is reduced. Various combinations of bauxite and calcium-producing materials can be used, and several heating methods are possible.

Aluminous cements are characteristically slow setting but are generally considered to provide high-strength material.

POZZOLANS

Pozzolans do not necessarily hydraulic set themselves, but they provide hydraulic-setting properties when combined with lime or portland cement. Natural pozzolans include certain volcanic glasses, pumices, tuffs, and high-silica-content materials such as diatomite. Some manufactured products, such as fly ash, are also considered pozzolans.

These materials may be used as extenders or with other hydraulic-setting materials. Lime alone has been used for centuries with various naturally occurring pozzolans. Properties developed will depend on the combination and amounts of pozzolans and lime or portland cement used.

MAGNESIA

Magnesia forms the basis for the so-called Sorel cements formed from a combination of magnesium oxide and a solution of magnesium sulfate. These materials, mixed together to form a binder slurry, react through a crystallization process. Magnesia can be replaced to some extent by calcined dolomite to provide wide latitude in raw material source.

These cements offer suitable strength as binders for roofing materials; magnesium oxychloride, particularly, is used to bind wood fiber into a board. However, the water sensitivity of these cements must be considered in any roofing application.

RECOMMENDATIONS FOR USE

Hydraulic-setting binders combined with various fibers and fillers should find application in preparing various types of roofing material—planks, boards, blocks, shingles, etc. Because of the nature of the setting mechanisms,

hydration and crystallization, hydraulic-setting binders must form a substantial portion of the composition. In addition, the density of the composition is usually high, otherwise strength will suffer.

Hydraulic-setting binders, except in the very densest uses or where slopes are such that drainage is rapid, do not waterproof, and some may deteriorate, usually by losing strength, when wet. Thus, this class of binder generally must be used with additional waterproofing, made extremely dense, or installed on slopes steep enough to allow quick drainage.

Hydraulic-setting binders are slurried with water and mixed with fiber, filler, etc., and the resulting mix is formed in a mold or press. Just enough water to slurry and mix should be used, since excess water adversely affects strength. The formed roofing material must be cured, for several days or weeks, to develop optimum strength. Either damp curing at ambient temperatures or various elevated-temperature processes may be used to speed the cure. After cure, the finished product is dried.

Appendix F. Asphalt Binders

ASPHALT

Asphalts and asphaltic substances have been used by man since the dawn of recorded history. They offer excellent binding qualities along with good weathering and waterproofing properties. Asphalt is derived from many sources including the distillation of petroleum, naturally occurring deposits (e.g., Trinidad Lake), and deposits of harder materials such as gilsonite found in seams and mined out of the ground. Asphalt is available with a wide range of properties from soft and sticky to hard and brittle and is made workable by heat, solution, or emulsification. Useful binders for roofing materials can be made by all three methods.

Asphalt or asphaltic substances can be mixed with a wide variety of materials to provide waterproofing coatings or mastics, or to function as binders for fibrous sheets or boards.

TARS AND PITCHES

Tars are the volatile oily decomposition products from heat processing of bituminous and other organic substances. Pitches are the residues resulting

Contributed by C. E. Bushnell, Manager, Building Products Research Unit, Armstrong Cork Company, Research and Development Center, Lancaster, Pennsylvania.

from the distillation of tars. Some materials useful as binders for roofing materials are tars and pitches from petroleum, coal, wood, rosin, peat and lignite, shale, fatty acids, bone, and other similar materials.

All these materials have characteristic properties and will vary in such things as waterproofness and weatherproofness, softness, brittleness, etc. Most are thermoplastic, but some have thermosetting or drying qualities that further enhance their usefulness. However, none would be considered highly developed in these respects. Any source of tar or pitch could usefully be explored as a basis for a roofing-material binder.

Appendix G. Agricultural and Wood Wastes

Solutions to the roofing problem in the developing world are needed urgently. Therefore a logical start for R&D is in areas that maximize the use of materials that are already available (and cheap) in developing countries, such as agricultural and wood wastes.

For example, locally available wood-wastes and agricultural wastes could be used to manufacture particle-board type roofing panels.[1] Research to develop roofing materials for low-cost dwellings might very well concentrate on one or more of the chemicals, present in wood and agricultural wastes, that could serve as binders.

Prime candidates are lignin and furfural. Lignin is a major ingredient in higher plants, where it binds together cellulose fibers to form the rigid woody structure. The lignin content of some plant materials that are widely available in most countries is shown in Table G-1. Furfural, too, is widely available from most agricultural wastes, which are used even in industrialized countries for the production of commercial furfural. Table G-2 shows the furfural content of some representative vegetable materials.

Considerable data are available on the use of lignin as a binder in plastics and laminated boards,[2] as well as for its use with phenolic resins, a combination which is claimed to be suitable as a wood particle-board binder. (See references at end of appendix.) Furfural also is used as an ingredient in in-

dustrial resin, especially the phenol-aldehyde type. Furthermore, it itself reacts readily with lignin, and, in the USSR, a lignin-furfural resin has been developed and used as a binder for molded wood products with encouraging results.[3]

Research aimed at developing cheap roofing suitable for developing countries might take advantage of the lignin binders already present in agricultural wastes. Research to explore using lignins alone or combined with furfural as binding agents in a particle-board type of roofing panel could be productive at this time. Of course, the furfural could also be obtained from agricultural wastes; thus, both binders could be produced from inexpensive waste materials already available locally in developing countries.

Building panels have been manufactured from agricultural and wood wastes for a number of years, and the following three general types are commercially available: hardboard, insulation board, and particle board (chipboard).

Hardboard panels, such as Masonite, have excellent physical properties and

TABLE G-2. Furfural Content of Miscellaneous Agricultural Wastes

have been used in some instances for the exteriors of housing in developed countries. Their ingredients can be cheaper than those of particle board, since a synthetic resin binder is not required. Hardboard, however, is usually pressed from wood fibers prepared by either the Masonite or Asplund processes, both of which require wood chipping, softening, defibrillating, and wet-sheet forming operations prior to panel pressing. Together these make a complex and costly process requiring, for developing countries, a high investment in equipment and plants. As a result, hardboard is not now manufactured in most developing countries and is an imported item even though suitable ingredients may be available locally. If lower cost processing can be achieved this might be changed.

The other two products, insulation boards and particle boards, have good physical characteristics and, with chemical additives, can be made resistant to fungus and insects. Particle boards have been made successfully from a variety of agricultural wastes as well as, more conventionally, from wood chips. The process is relatively simple, and particle board is now manufactured in some developing areas (e.g., Central America). The cost of these locally produced panels, however, is too high for it to be an ideal construction material for low-cost housing in developing areas. A major contributor to this cost is the synthetic-resin binder of petrochemical origin, which in many areas must be imported or produced locally from imported raw materials and which is required by current processing techniques.

Data published by the Food and Agriculture Organization (FAO) in 1957[4] on the production costs of three types of European-manufactured particle board indicate that raw material costs (wood scraps and resin) represent from 52 to 63 percent of the total manufacturing cost of the product. In Central America a particle-board panel made from wood chips and measuring 4 ft wide by 8 ft long and 1½ in. thick sells for $0.35 per square foot, and it is estimated that the resin binder represents over 50 percent of the total material cost in the manufacture of the particle board.

These costs suggest strongly that a low-cost building panel suitable for developing countries could be developed if processing costs could be reduced. This could be accomplished if the need for an imported synthetic resin binder could be eliminated from the particle-board manufacturing process.

Ideally presses of the type already developed for particle-board manufacture could be used. Because of the special requirements of most tropical countries, additives to enhance the insect and fungus resistance of, and to waterproof, the finished product will be necessary, but conventional chemical products currently used for these purposes may prove adequate. This approach is versatile and, in concept, could produce panels for roofing and for the exterior and interior walls of low-cost housing in both rural and urban areas. For the different uses, however, different densities may be re-

quired. For example, for roofing a low-density panel might be needed so that it could be saturated with a waterproofer such as asphalt.

Research directed toward this end might investigate new cheap, mechanical and chemical, methods for releasing lignin from woody materials. Lignin alone or in combination with furfural would have to be submitted to the usual tests of production pressure, temperature, and time and their relation to product quality.

Most developing countries lack research facilities and experienced personnel, especially in the specific case of lignin research. Although lignin has been extensively studied in industrialized countries, research for low-cost roofing materials might best be conducted in the more developed countries. However, the raw materials and the demographic, climatic, and other conditions are different in developing countries. It seems more reasonable to conduct new process development work in developing-country facilities and to appoint a principal investigator who has previously worked with lignin and is familiar with the manufacturing process of hardboard and particle board. Developing-country investigators could participate and not only learn and develop processes but also contribute significantly by supplying local statistics and such information as the availability and accessibility of suitable raw materials. In addition to laboratory equipment, a pilot-plant installation for particle-board manufacture would be desirable.

Appendix H. Ferrocement

Ferrocement was not discussed by the committee because BOSTID had under way an in-depth review of ferrocement's potential for developing countries, which included its use for roofing. Since the committee's meeting, the ferrocement panel has published a report. Their evaluation of ferrocement is quoted here.

Ferrocement is a highly versatile form of reinforced concrete made of wire mesh, sand, water, and cement, which possesses unique qualities of strength and serviceability. It can be constructed with a minimum of skilled labor and utilizes readily available materials. Proven suitable for boatbuilding, it has many other tested or potential applications in agriculture, industry, and housing.

Ferrocement is particularly suited to developing countries for the following reasons:

- Its basic raw materials are available in most countries.
- It can be fabricated into almost any shape to meet the needs of the user; traditional designs can be reproduced and often improved. Properly fabricated, it is more durable than most woods and much cheaper than imported steel, and it can be used as a substitute for these materials in many applications.
- The skills for ferrocement construction are quickly acquired, and include many skills traditional in developing countries. Ferrocement construction does not need heavy plant or machinery; it is labor-intensive. Except for sophisticated and highly stressed designs, as those for deep-water vessels, a trained supervisor can achieve the requisite amount of quality control using fairly unskilled labor for the fabrication.[1]

The panel believes that ferrocement may prove a suitable material for low-cost roofing in developing countries. Applied-science laboratories in developing countries and technical assistance agencies should seriously consider this area for field trials and techno-economic studies. . . .

Ferrocement represents a potential solution to roofing problems because of its relatively low cost, durability, weather-resistance, and particularly its versatility. Unlike most conventional materials, ferrocement can be easily shaped into domes, vaults, extruded type shapes, flat surfaces, or free-form areas. Because ferrocement is easily fabricated, even in rural areas, by supervised local labor using mainly indigenous materials, it seems an excellent medium for on-the-site manufacture of small or large tiles (shingles) or other roofing elements. Where wooden timbers are very expensive, ferrocement beams might be made on site to replace wooden structures used to support indigenous roof coverings. Its most economical use, however, appears to be for fairly large-span roofs.

Ferrocement is not commonly used for roofing because its promise has not generally been recognized. Its use, particularly in developing countries, must be preceded by more research and experimentation in design and production techniques suited to construction by unskilled labor.[2]

Ferrocement roofing materials can be factory mass-produced in prefabricated form, a process best suited to the concentrated demand of urban areas. Though it might be more economical to mass-produce roofing in an urban factory and truck it to a rural area (should trucking be possible), ferrocement is also easily fabricated on site in rural areas, using local labor and materials.

Freer in concept and makeup than most conventional roofing, ferrocement can be shaped into domes, vaults, extruded shapes, flat surfaces, or free-form areas.

Before ferrocement can be used widely for roofing, research and experiments will be required to determine the shapes and types of roofing members to be manufactured, and to explore designs and methods for anchoring and bolting these various shapes to supporting walls.

After this research and experimentation is completed, on-the-job training centers may be required to introduce the new material and its new building techniques. Preferably, these centers should also offer programs dealing with other ferrocement applications.

Research efforts to find ferrocement modifications that prove less expensive or easier to manufacture are highly recommended. Possibly, for example, ferrocement can be sandwiched on two sides of a core of foam concrete or other lightweight material to make a less expensive and lightweight, yet still structurally strong, material.[3]

Appendix I. Low-Cost Roofing Research in India

Over the years, roofing problems have been studied in depth at the Central Building Research Institute of India (CBRI) and are briefly described in the appendix.

CLAY

Clay roofs are common in developing countries because of the availability of clay and the low construction costs. In India, these include flat mud roofs, country-tiled roofs, and Mongalore-pattern clay tile roofs.

Research and development activities at CBRI have added several new techniques: (1) precast *Guna* clay tile units, (2) corrugated-clay roofing sheets, (3) structural-clay flooring/roofing units, (4) reinforced brick, and (5) reinforced-brick concrete. The salient features of these techniques are described below.

PRE-CAST GUNA CLAY TILE UNITS

Guna tile is a hollow, conical clay tile. A unit of the roofing system is about 110 cm long, 25 cm wide, and 12 mm deep (43.31 X 9.84 X 0.47 in.) and

Contributed by Professor Dinesh Mohan, Director, Central Building Research Institute, Roorkee, Uttar Pradesh, India.

weighs nearly 41 kg (90.40 lb). Compared with a conventional 10-cm (3.94-in.) reinforced concrete (RCC) slab, the saving in use of cement is 28 percent and of steel, 55 percent.

CORRUGATED-CLAY ROOFING SHEETS

A process has been developed for producing corrugated-clay roofing sheets (105 cm × 60 cm × 10 mm or 41.34 × 23.6 × 0.39 in.) from specially processed clay mix. These sheets do not warp or crack during drying and firing, and the process is simple enough to be implemented with hand labor in villages. The tensile strength of these sheets lies in the range 100–105 kg/cm^2 (1422–1493 psi), and water absorption is below 2 percent. Each sheet weighs about 15 kg (33.07 lb).

STRUCTURAL-CLAY FLOORING/ROOFING UNITS

In several developing countries, mechanized brick production is increasing. Taking advantage of this situation, CBRI has developed two types of structural flooring/roofing units. Plastic alluvial clays (kaolinite-illite mixtures) with a fairly wide range of workability are suitable for extruding these tiles. Tiles are pre-assembled on the floor: the units are placed end to end up to the required length, a 6-mm (0.24-in.) mortar joint being provided between the tiles. A triangular cage of mild steel bars is placed within the hollow space provided in the tile for the purpose, and it is then concreted. After concreting is done, two beams are placed on bearing walls at 45-cm (17.72-in.) centers and the intervening space filled up by placing ceramic blocks of the same design in an inverted position. A deck concrete is laid on to a thickness of 3 cm (1.18 in.). Compared with a conventional 10-cm (3.9-in.) RCC slab, the system is estimated to save 40 percent in cement consumption and 30 percent in steel. Deck concrete can be eliminated by slight modification of the design, thereby effecting further economy in cement consumption.

Tiles of another design have been developed for vertical construction of floor sections in the manner of a masonry wall. After the wall panels have acquired adequate strength, they are tilted to a horizontal position to form a flooring unit and placed on the bearing walls. This type of clay tile is likely to result in an economy of 60 percent in cement and 30 percent in steel, compared with a conventional RCC slab.

REINFORCED BRICK (RB)

Reinforced brick has essentially the same features as reinforced concrete, except that brickwork in cement mortar is substituted for cement-concrete.

Reinforcement is placed in the mortar joints, which are generally 2.5 to 3 cm (0.98-1.18 in.) wide. All other joints with no reinforcement are generally 1 to 1.2 cm (0.39-0.47 in.) wide. Good-quality bricks with a minimum strength of 70 kg/cm^2 (995.4 psi) should, however, be used. These bricks are of medium absorption (8-15 percent) and free from any trace of smooth glaze on the surface. The mortar used is 1:3 (cement:sand).

RB slabs may be designed for both one-way or two-way spanning. The design principles are the same as those for reinforced concrete, except that the permissible stresses and other design factors are different. For normal residential buildings, this type of slab has yielded a saving of about 10 percent compared with an RCC slab.

REINFORCED BRICK CONCRETE (RBC)

In this type, cement-concrete is used in conjunction with the bricks as a deck over the top surface of the bricks, as well as for filling the joints. The thickness of deck concrete generally varies from 4 to 6 cm (1.57-2.36 in.) and the joint thickness from 4 to 5 cm (1.57-1.97 in.). In general, the deck concrete at the top forms the compression zone, whereas the participation of brick in resisting compression is either nil or very limited. RBC slabs are also designed like RCC slabs and are used quite extensively in India as an alternative to RCC slabs for floors and roofs of residential buildings.

ORGANIC MATERIALS

Organic materials such as wood, thatch, and leaves are very commonly used for roofing purposes in developing countries. In India, thatched roofs are built of locally available grass or palm leaves. The roof is supported on wooden posts and rafters and is tied to suitably spaced bamboo battens. The incline of the roof depends on the intensity of rainfall and is usually 30-45°. This type of roofing is most popular in villages because of its cheapness and the ease and rapidity of its construction. In the tropics, however, thatch deteriorates rapidly and harbors insects. It also presents a serious fire hazard. Chemicals are available to improve the durability of thatch and render it fireproof, but they leach away during rains and need reapplication. CBRI has developed a stabilized mud plaster, which is applied on the lower surface of a thatch roof to reduce its rate of burning. The risk of fire spreading from one roof to the next is reduced by the application of a thin wash of stabilized mud on top of the roof. This mud wash, however, needs renewal after each monsoon, especially on palm-leaf roofs.

CBRI investigations have confirmed the possibilities of preparing a roof-

ing board based on particle boards prepared from the husks of mature coconuts. A board of density (753 kg/m^3 or 47.1 lb/ft^3), prepared with 0.5 percent P.F. resin adhesive, possesses modulus of rupture, in bending, of 232 kg/cm^2 (3299 psi). These boards can be rendered waterproof with cashew-nut-shell liquid. Tests have shown that they are self-extinguishing and need no fire-retardant treatments. CBRI has also developed a chipping machine, specially adapted for chipping the husks of mature coconuts. Because of the widespread availability of coconut husks in most developing countries, it could become a profitable source of roofing material and other products.

Corrugated-asphalt roofing sheets have recently been introduced in India. They tend to delaminate at the edges, and their dark color absorbs solar radiation and renders the internal environment uncomfortable. White-washing roofs helps to reflect the solar radiation and cools the ceiling by 2 to 3 °C.

CONCRETE

In building a strong base for industrialization, several developing countries are experiencing rapid urbanization of the countryside. In such a situation, judicious use of cement and steel can help to provide economic alternatives for the conventional in situ RCC slab. If the new techniques lend themselves to simple prefabrication, they could also help in mass housing programs. In CBRI several roofing units have been developed that economize in the consumption of cement and steel and can easily be precast at a factory or at the construction site. Some of these units are described below.

PRECAST DOUBLY CURVED TILE UNITS

The concrete tile unit is square–68.6 cm X 68.6 cm X 19 mm (2.25 ft X 2.25 ft X 0.75 in.). Its surface is curved in both directions, which enhances its resistance to both sustained and impact loads. It weighs only 27.2 kg (59.98 lb), and no reinforcement is needed in the edge beams. The casting process is very simple: To construct the roof, precast RCC beams are laid at 76.2-cm (30-in.) centers and provided with two temporary wooden props at middle-third points along the length. The tiles are laid on a bed of mortar put on the beam edges and carefully positioned. The haunches are next filled up with the cement concrete, leaving only a small ridge uncovered. The waterproofing-cum-insulating treatment is then provided over the roof in the con-

ventional manner. The roof is suitable for single-story schools, offices, and residential buildings where it is not likely to be subjected to a concentrated or heavy load and the spans do not exceed 4.25 m (13.94 ft). It results in substantial savings in cost, as well as in the consumption of cement and steel. For example, at a site in Delhi, the saving in the consumption of cement was 25 percent and of steel, 25 percent, compared with the conventional RCC slab.

PRECAST CELLULAR UNITS

These rectangular, concrete units could be used for roofs and floors. The unit size is 1 m X 0.5 m X 100 mm (3.28 X 1.64 X 0.33 ft), and it weighs nearly 55 kg (121 lb). It is provided with three to four hollow, hexagonal cells, running through its entire length. The unit is cast with the help of single timber formwork and provided with hexagonal slots at the two ends through which timber forms for creating the hollow cells are inserted.

For casting the roof, the units are placed on either rectangular beams or composite T-beams. Most beams are precast T-beams; temporary propping is needed. With rectangular beams, however, construction is relatively simple, and no supports are necessary during the construction, nor is reinforcement needed in the top concrete. With either type of beam, it is necessary to lay a minimum of 35 mm of lean concrete on top of the units to enhance their resistance to impact loading. The complete roof assembly has been tested and found suitable for a load of 0.19 kg/cm^2 (400 lb/ft^2). Compared with conventional RCC slabs, the percentage savings in the consumption of cement are about 30 percent and of steel, 70 percent, when rectangular beams are used to support the units. With T-beams, the corresponding savings are 20 and 50 percent.

CORED UNITS FOR ROOFING

CBRI has also developed prefabricated-concrete, doubled-cored units that provide a flush ceiling. They need no temporary propping. The units weigh about 136 kg (299.88 lb), and their dimensions are 30 cm X 12.7 cm X 3.7 mm (11.81 X 4.99 X 0.15 in.). Recently, a prototype of a machine using a pressure-cum-vibration technique has been developed at CBRI for casting concrete-cored units up to 61 cm (2.5 ft) in width and of various shapes and sizes.

The use of these units could effect savings of 15 percent in cement and 10 percent in steel, compared with the conventional 10-cm (3.94-in.) RCC slab (3.7-m or 12.14-ft span).

PRECAST-CHANNEL UNIT FLOORING/ROOFING SYSTEM

A precast RCC element, trough-shaped in section, the unit is structurally complete in itself and does not need propping during construction. It is generally 300 mm (11.91 in.) wide, 125 mm (4.92 in.) deep (the depth may vary depending upon the span and loading), and is 2.4 to 4.2 m (7.87–13.78 ft) long. The length can also be adjusted to suit the span. The shape of the unit allows for space between adjacent units for negative reinforcement over supports and laying of concrete in situ, which develops a monolithic structure and permits flexibility in designing the floor/roof as a continuous one-way slab. The wooden molds for the units are made of an outer rectangular frame and a trough-shaped inner frame. The units are precast with the flange on the underside and the ribs on the upperside and in the usual manner of casting concrete members. A unit 300 mm × 125 mm and 3.6 m long (11.81 × 4.92 × 141.73 in.) weighs about 122 kg (268.91 lb). A comparative-cost study of a continuous (3 bays of 3.5 m, or 11.48 ft, each) conventional RCC roof slab and a channel-unit roof of the same dimensions revealed almost no saving in steel, but saving in cement is about 40 percent.

PRECAST-CONCRETE WAFFLE UNITS

Recently, a scheme for precast-concrete grid floors and roofs for longer spans was developed at CBRI. It consists of waffle units 0.6 m^2 (6.46 ft^2) laid in a grid pattern. The reinforcements are laid in the gaps between the units, and concrete is placed to act as grid beams in two mutually perpendicular directions. The shape of the units was worked out to ensure load transfer from one unit to the adjacent one through the in situ concrete between them. Elimination of in situ deck concrete above the units is a distinct feature of the system. This system results in a saving of about 8 percent in steel and 30 percent in concrete, compared with the conventional 10-cm (3.94-in.) RCC slab of equal span.

MISCELLANEOUS MATERIALS

Metals, such as galvanized iron and aluminum, and minerals, such as natural stone, asbestos, etc., are also used for roofing in the developing countries. The use of corrugated aluminum sheets is gaining ground in Africa, the southeast Asian region, and Argentina. They improve physical comfort to some extent because of their high heat-reflecting factor in the initial stages. Roof framing is of the rafter and purlin type.

Slate roofs are generally adopted in hilly areas of India. They are laid over wooden trusses and purlins. The slates are normally 61 cm X 91.4 cm X 215 cm (2 ft X 3 ft X 1 in.) in size. Asbestos-cement corrugated sheets are also very commonly used for roofing in India. For this purpose, the chrysotile variety of asbestos is imported each year at a cost of Rs. 100 millions (U.S. $14 million). To conserve foreign exchange, the CBRI has developed a process for full or partial replacement of imported chrysotile with indigenous amphibole asbestos.

Appendix J. Potential Roofing Materials and Composites

During the committee's deliberations many materials were identified that might be considered when planning a research program to solve developing country roofing problems. The following list was developed by the panel early in their meeting. Because of time limitations no consideration was taken of the practicality of any of the materials (e.g., durability, pest resistance, strength). This list is included here only to convey a sense of the range of materials locally available in the developing world whose properties may make them worth considering for use in low-cost roofing research projects. For completeness, some materials already in standard use are included.

The list is divided into the following categories.

1. General roofing materials
2. Potential components of composite roofing materials
   binders
   reinforcement
   fillers/aggregates
   coatings

1 GENERAL MATERIALS THAT MIGHT BE USED FOR LOW-COST ROOFING IN DEVELOPING COUNTRIES

Plastic (as sheet, perhaps as a fiber in an "artificial thatch," or foamed or formed)

Bituminous products (either formed, built-up or as shingles)
Concrete (e.g., reinforced, ferrocement, foamed concrete, lightweight aggregate concrete)
Minerals (e.g., slate, stone, gypsum)
Formed clay products (e.g., as tiles or sheets)
Other materials from soil (perhaps stabilized or foamed)
Wood products [e.g., shingles/tiles, plywood, particle board, wood wool (wood fibers in concrete) or formed paper]
Vegetable products (as thatch or woven mats, e.g., grass and reeds, canes, bamboo)
Fabrics (e.g., canvas)
Animal products (e.g., leather, hides)

2 POTENTIAL COMPONENTS OF COMPOSITE MATERIALS

BINDERS

Portland cement
Other hydraulic-setting cements (e.g., products from blast furnace slag, fly ash)
Clay, calcinated clay, earth, etc.
Limestone, lime or gypsum
Magnesium oxychloride sulfate
Glass
Sulfur
Asphalt, coal tar derivatives, and petroleum derivatives
Pitches, rosins and gums (e.g., tall oil pitch, cottonseed pitch, soya bean oil residue)
Lignins, furfural
Starches (e.g., from grains or root crops)
Oils (e.g., drying oils such as linseed or cashew-nut-shell liquid, with or without catalyst)
Rubber and natural latex
Adhesive proteins [e.g., casein, animal and fish blood, legume protein, bone/hoof glue (animal glue and tannery waste)]
Animal grease
Silicates [e.g., sodium silicate (water glass)]
Plastic resins
- Unsaturated polyesters, polyolefins, etc.
- Urethanes
- Urea-formaldehyde

Other thermoplastics
Shellac

REINFORCEMENT

Metal (rod, fiber, wire mesh, "expanded" metal)
Mineral fibers (asbestos; wallostonite; amphibole; long fiber chrysotile; rock wool from blast furnace slag; glass fibers)
Vegetable waste (e.g., rice hulls; bagasse; cottonseed; peanut hulls and other seed hulls; cotton, jute, sisal and other textile-fiber wastes; coconut husks; straw)

COATINGS

Sulfur
Polymers/paints
Metal coatings (e.g., galvanized or metal foil)
Silicones
Cashew-nut-shell liquid
Bituminous products
Mineral particulates
Whitewash
Sand

FILLERS/AGGREGATES

Sand, soil, rock and clay
Expanded (bloated) clays, expanded shale, expanded perlite, expanded slag and glass
Sintered fly ash
Shells
Pozzolans
Diatomaceous earth
Waste glass
Air (as in foams)
Organic materials [e.g., bark; wood (sawdust, chips); cork and pitch, paper, coconut shell]
Carbonized plant products (charcoal expanded husks, cereal grains, seed hulls, etc.)

ESPAÑOL

Recomendaciones

El propósito de este informe es identificar una amplia variedad de materiales que los investigadores científicos pueden considerar en su selección para un nuevo sistema de techos en los países en desarrollo. Como las particularidades, necesidades, clima y disponibilidad de materiales y recursos de los países en desarrollo difieren extensamente, cada uno de ellos debe determinar independientemente cuáles de los cursos de investigación son los más promisores. Sin embargo, el comité cree que un plan organizado y sistemático en el establecimiento y finalidades de los programas de investigación e implementación dentro de los países en desarrollo puede conducir a prontos resultados para su utilización inmediata, en todos los países o al menos en la mayoría.*

1. COMITÉ ASESOR INTERNACIONAL

Debería establecerse un comité asesor permanente bajo el auspicio internacional apropiado. Sus esfuerzos deberían encauzarse específicamente a acelerar, expandir y consolidar los bien dispersos programas existentes de

*Este informe fue terminado antes del reciente aumento en los precios del petróleo crudo. Substancialmente el aumento de costos de los derivados del petróleo les afectará adversamente su posición competitiva con los adhesivos poliméricos y plásticos porosos (recomendaciones 2 y 3) aumentando la preferencia por las tecnologías que no hacen uso de subproductos del petróleo, discutidas en las recomendaciones 4 y 10.

investigación para techos de bajo costo en los países en desarrollo. El comité debería concentrarse en enfocar el problema desde el punto de vista global y no simplemente regional.

Típicamente el comité debería encausar la necesidad de efectuar un inventario de los materiales para techo y de las prácticas de diseño y construcción actualmente utilizados en los países en desarrollo, como también de los problemas que en la actualidad están siendo estudiados por esos países y otras organizaciones investigativas. Este inventario deberá facilitar la identificación de áreas aun no cubiertas en la investigación y de aquellas que requieren mayor atención.

La mayoría de los miembros del comité deberían ser expertos en vivienda para las regiones en desarrollo y otros deberían proceder de las más apropiadas organizaciones mundiales académicas e investigativas y de organizaciones de ayuda técnica que tengan un interés substancial y recursos considerables dedicados al aspecto de la vivienda en los países en desarrollo (tales como AID, Banco Mundial, Programa de Desarrollo de las Naciones Unidas, Centro de Planificación, Construcción y Vivienda de las Naciones Unidas, Banco Interamericano de Desarrollo, Organización de Estados Americanos y CARE.

2. CONGLOMERANTES POLIMÉRICOS

Los programas de investigación, demostración y desarrollo para cubierta de techos deberán encauzarse al uso de poliésteres no saturados y polímeros apropiados, existentes comercialmente, para producir combinaciones aglutinantes con materias primas (v.g. fibras vegetales, entelados y tierras) de los países en desarrollo seleccionados.

Estos esfuerzos pueden ser productivos porque actualmente la tecnología para productos empleados en la fabricación de edificios, usando fraguación térmica (v.g. poliésteres no saturados), resinas termoplásticas y polímeros correspondientes en combinación con otros materiales, está altamente desarrollada y bien documentada (véase apéndice A). Si estos productos son compatibles y pueden mezclarse con las materias primas disponibles localmente, será posible fabricar piezas de formas y dimensiones ilimitadas para satisfacer los diseños requeridos por las diferentes tradiciones y costumbres. El comité piensa que mediante un programa concertado de desarrollo y prueba, a nivel piloto se podrían producir materiales compuestos apropiados para sistemas de techo a bajo costo en la mayoría de los países en desarrollo.

La tarea mayor en desarrollar compuestos de bajo costo que puedan resistir elementos destructivos tales como humedad, rayos ultravioleta, fungus e insectos. Deberá darse especial énfasis a la identificación de los peligros potenciales asociados con el uso de productos de materiales plásticos. Por ejemplo, si se cocina con llama abierta en el interior de la vivienda, ciertos elementos plásticos del techo pueden inflamarse y producir humos dañinos o gases tóxicos. Los polímeros pueden ser tratados mediante técnicas relativamente

simples para soportar la exposición directa al fuego, pero hasta ahora la aplicación de estos polímeros tratados ha sido relativamente costosa.

Si se pueden elaborar materiales a un costo razonable y de alta confiabilidad, la tecnología de su fabricación probablemente podría ser transferida con poca dificultad a los países en desarrollo; la simplicidad en producir materiales de resina sintética para techos permitiría una fácil difusión de la tecnología y su pronta comercialización por empresas pequeñas. Los productos para terminación de edificios prometen competir económicamente con el hierro corrugado, inclusive ofrecen un precio más conveniente.

Los costos de fabricación de los compuestos para techos pueden ser muy bajos. El sistema sería versátil y se prestaría a una intensiva producción manual.

En su estado crudo, las resinas y polímeros básicos son estables pudiendo ser almacenados por cierto tiempo, pero para mantener sus características específicas deben mantenerse en un sitio frío y a la sombra. Como estos están concentrados, sólo requieren un espacio limitado para su transporte y almacenamiento y su valor intrínseco es muy pequeño hasta ser convertido en material de construcción. Si dentro de los países en desarrollo no se dispone de polímeros y resinas básicas, estos tendrían que ser importados pero probablemente sólo representarían una porción inferior a la del costo del techo terminado. No existen problemas de logística de importancia en la importación de resinas y polímeros a granel—existen numerosos fabricantes y abundante aprovisionamiento—ni tampoco es dificultuoso manejarlo, almacenarlo o transportarlo a su sitio de uso final.

Los estudios investigativos concernientes a este tipo de aplicación deberán incluir un análisis de costos-beneficios entre las resinas importadas y las alternativas opuestas, tales como el hierro corrugado importado.

3. PROCESAMIENTO DE PLÁSTICOS POROSOS

Deberá iniciarse un proyecto piloto para el procesamiento de materiales a base de plástico poroso apropiado para cubrir techos y para la fabricación de un equipo móvil a pequeña escala y cuya producción pueda resultar económico en los países en desarrollo.

Los plásticos porosos de baja densidad son substancias celulares producidas por la inyección de burbujas de gas durante la fabricación de compuestos plásticos—que representan un significativo potencial como material versátil, de peso liviano y alto aislamiento para techos y que puede ser producido en el sitio de la obra en una variedad de formas y dimensiones (véase apéndice B). Hasta la fecha el uso de plástico poroso ha sido limitado severamente por falta de un equipo mezclador sencillo, confiable y de bajo costo, capaz de elaborar un producto uniforme de alta calidad.

El equipo usual para procesar plástico poroso genera químicamente la espuma y luego distribuye, por pulverización, la masa congelante de finas

burbujas en la posición deseada. En el pasado el equipo de procesamiento usado para este tipo de demostraciones en los países en desarrollo, era bastante complicado y sensitivo, y requería un mantenimiento costoso. Sin embargo, los últimos adelantos en el diseño de equipos ha eliminado muchos de los problemas experimentados anteriormente. En consecuencia parece ser que esta es la oportunidad más apropiada para incorporar tales avances en el desarrollo de un sistema mezclador móvil y de pequeña escala que pueda ser producido en masa por los países en desarrollo. Este sistema en combinación con una demostración que pruebe que los plásticos porosos pueden ser utilizados para agregar rellenos y capas de refuerzos como material para capas inferiores y de cubierta para techos, puede dar lugar a la formación de empresas lucrativas locales que podrían producir el equipo y diversos productos de plástico poroso.

El proyecto piloto recomendado deberá ser organizado claramente como un experimento para evaluar y documentar el rendimiento del equipo, así como su economía, aceptación por el consumidor, uso, longevidad y durabilidad de los techos prototipos producidos. El proyecto puede ser perfectamente conducido como un esfuerzo cooperativo entre empresas de los EE.UU. y de los países en desarrollo, con participación de instituciones académicas, organizaciones comerciales y profesionales de la industria constructura, más la asistencia técnica de organismos especializados en vivienda.

Debe hacerse notar que recientemente "the U.S. Federal Trade Commission" estableció que ciertos productos plásticos de poliuretano y poliestereno usados en construcción de viviendas pueden ser peligrosos para la salud y la vida cuando se exponen al fuego. Este hecho es bien conocido por los técnicos en vivienda. Sin embargo ahora existen ciertos plásticos con baja producción de humo y propagación de llama, y se esperan mayores progresos en el futuro. A pesar de ello, los investigadores dedicados al desarrollo de materiales plásticos para techos en los países en desarrollo deberán estar advertidos de los peligros potenciales relacionados con el fuego y deberán mantenerse informados de los adelantos técnicos en esta materia.

4. AZUFRE

Debe prestarse seria consideración al empleo del azufre como material aglutinante para otros materiales nativos, como capa de revestimiento, como material para relleno de junturas y para la fabricación de productos pequeños para techos, por ejemplo, tejas.

A pesar que el azufre no ha sido usado extensivamente como material para construcciones, su empleo tiene muchas aplicaciones para techos a bajo costo en los paises en desarrollo, que deben ser exploradas (véase apéndice C). El uso de este material para fines de construcción en los países en desarrollo ha estado sujeto a una comprensiva investigación científica, en la última década. Su uso en tales países es particularmente digno de consideración en vista de

la abundante existencia de azufre debido a las actividades volcánicas y a ser un subproducto del petróleo. El azufre puede constituir un artículo de importación a bajo costo para aquellos países que carecen de azufre en estado natural.

Las pruebas e investigaciones previas han sido dirigidas principalmente a su empleo como agente adhesivo de superficie en el concreto sulfurado. El azufre elemental es un agente aglutinante con propiedades únicas: Su punto de fusión es 240°F, ligeramente superior al del agua; es insoluble en agua, teniendo propiedades de impermeabilización; es inodoro; no produce efectos tóxicos en su uso normal; es un mal deficiente conductor del calor; su vida de almacenamiento es ilimitada y puede ser procesada nuevamente. Todas estas características indican un excelente potencial para su uso como material para techos en los países en desarrollo.

El azufre elemental es particularmente apropiado para métodos de construcción de trabajo pesado teniendo ciertas limitaciones: es altamente inflamable y debe ser convertido a estado líquido antes de añadir agregados o rellenadores. Los fabricantes y aquellos que lo usan deben estar prevenidos del posible desprendimiento de acido sulfúrico en presencia de las humedad, así como de sus efectos perniciosos si llega a ser ingerido. Sin embargo, sus ventajas sobrepasan las desventajas, justificando todo esfuerzo de desarrollo e investigación en la actualidad.

5. MATERIALES DE PLANTAS CARBONIZADAS

Se deberán efectuar estudios investigativos de laboratorio y demostraciones concernientes a la transformación de resinas poliésteres no saturadas y polímeros relativos combinados con productos de plantas ricas en almidón, no comestibles carbonizadas y expandidas (véase el apéndice G) en planchas para techos de peso liviano y de bajo costo. La investigación deberá incluir la identificación de tipos y cantidades de los productos de plantas apropiadas para este propósito, así como su disponibilidad en los países en desarrollo.

6. RESIDUOS AGRÍCOLAS Y DE MADERA

Se deberá iniciar un programa extenso tendiente a desarrollar procesos económicos para la fabricación de resinas provenientes de productos agrícolas nativos (v.g. vegetación natural, residuos de caña) para ser utilizados principalmente como aglutinantes o adhesivos.

Como puede notarse en el apéndice G (Ref. 1) la lignina y furfural en vegetación pueden ser usados como adhesivos *in situ* si se les aplica presión y calor. Esta tecnología es bien conocida en los países industrializados y es probable que métodos de procesamiento simplificados puedan permitir a los países en desarrollo, producir una abundante cantidad de paneles apropiados para construcciones.

7. RESIDUOS DE INDUSTRIAS PRIMARIAS

Las cenizas y escoria del coque de los altos hornos empleados en la industria del acero tienen características que las hacen apropiadas para ser usadas como cementadores aglutinantes y deberán ser investigadas (véase el apéndice E). Estos residuos pueden ser de particular valor en aquellos países que carecen de piedras calizas y de recursos de cemento portland.

El "barro rojizo" que es un copioso subproducto de la refinación de la bauxita, abundante en muchos países en desarrollo, también merece seria consideración así como los residuos metálicos de la producción de hierro y acero. La eliminación de estos residuos y de otros productos similares constituye una carga constante para la industria pesada en todo el mundo; su conversión a productos útiles serviría un propósito doble. Las investigaciones para tales alternativas pueden atraer a las industrias afectadas hasta el punto de inducirlas a contribuir con fondos o materiales.

8. CONCRETO

Deberá efectuarse un programa analítico y de pruebas de laboratorio encaminado a desarrollar productos de concreto reforzado más económicos y apropiados (véase el apéndice H, hierro-cemento). Las investigaciones deberán concentrarse en el uso de materiales para refuerzos tales como malla de alambre, fibras de vidrio y lana pétrea disponibles localmente así como diferentes productos vegetales tales como bambú (Ref. 2), cortezas y fibras de madera (las fibras de madera se conocen en ciertas partes del mundo como "lana de madera" o "virutas de madera" (Ref. 3). También deberá prestarse consideración a los substitutos para cemento portland, algunos de los cuales se sugieren en el apéndice E.

9. MATERIALES A BASE DE ARCILLA

Se deberá conducir un programa de investigación para desarrollar métodos tendientes a mejorar el desempeño general y la amplitud de aplicaciones de los materiales a base de arcilla, greda o barro para techos (véase el apéndice I).

10. PRODUCTOS DE FIBRA

Deberá explorarse la conveniencia y efectividad del uso de residuos de las materias primas empleadas en la industria textil y otras industrias de fibras [basadas en fibras de yute, henequen (sisal), cáñamo, kenaf y algodón] que son comunes en los países en desarrollo, para aprovecharlos como mezcladores en un material compuesto para piezas de techos.

En resumen, existen numerosos medios promisorios de exploración y el comité asesor opina que es el momento de aprovechar al máximo estas ventajas.

FRANÇAIS

Recommandations

Ce rapport énumère une grande variété de matériaux qui pourraient intéresser des chercheurs pour la mise au point de nouveaux systèmes de couverture des toits dans les pays en voie de développement. Ces derniers ont des besoins, des climats, des matériaux et des ressources si différents qu'ils doivent déterminer individuellement les domaines dans lesquels la recherche apportera les meilleurs résultats. Cependant, le comité est d'avis que l'établissement et la direction de ces programmes de recherche et de développement devraient procéder d'une démarche systématique et organisée. Les pays en voie de développement obtiendraient ainsi des résultats immédiats qui pourraient être utilisés par la plupart d'entre eux, sinon par tous. Le comité propose donc les recommandations suivantes*:

1. UN COMITÉ CONSULTATIF INTERNATIONAL

Un comité consultatif permanent devrait être créé sous les auspices d'organisations internationales compétentes. Ses efforts devraient être particulièrement dirigés vers l'accélération, l'élargissement et la consolidation de programmes dispersés de recherche sur les toitures à bon marché qui existent

*Ce rapport a été terminé avant la recente augmentation des prix du pétrole brut. L'augmentation importante des prix des dérivés du pétrole se répercutera sur la concurrence des liants polymères et des mousses plastiques (recommandations 2 et 3) et augmentera l'attrait des techniques basées sur les produits qui no sont pas tirés du pétrole. Ces techniques sont examinées dans les recommandations 4 à 10.

déjà pour les pays en voie de développement. Le comité devrait mettre l'accent sur l'aspect régional plutôt que sur l'aspect mondial.

Représentatifs des besoins qu'un tel comité pourrait aborder seraient non seulement l'inventaire des matériaux de couverture, la conception et les pratiques de construction qui sont en usage dans les pays en voie de développement, mais aussi les problèmes de couverture des toits actuellement à l'étude dans ces pays et dans d'autres organismes de recherche. Un tel inventaire permettrait d'identifier tant les lacunes qui existent dans la recherche que les domaines qui réclament plus d'attention.

Le comité devrait être composé en majorité d'experts du logement venant des régions en voie de développement. Les autres membres devraient provenir d'organismes de recherche et d'établissements universitaires du monde entier et aussi d'organismes d'assistance technique dont l'intérêt majeur et les ressources considérables sont dirigés vers le logement dans les pays en voie de développement: l'AID; la Banque mondiale; le Programme des Nations Unies pour le développement; le Centre des Nations Unies pour le logement, la construction et la planification; la Banque interaméricaine de développement; l'Organisation des États américains; CARE, etc. . .

2. LIANTS POLYMÈRES

Les programmes de recherche, de mise au point et d'essais pratiques des couvertures et toitures, devraient être axés sur l'emploi des polyesters non-saturés et des polymères connexes existant sur le marché, comme liants dans les mélanges de matériaux produits localement, tels que les fibres végétales, des terres et des tissus en provenance de pays en voie de développement déterminés.

Un tel effort pourrait être productif actuellement puisque les techniques qui utilisent les résines thermoplastiques et thermodurcissables, les polyesters, par exemple, ainsi que les polymères connexes en combinaison avec d'autres substances pour la fabrication de matériaux de construction, sont parfaitement au point et tout à fait documentées (voir annexe A). Si de tels produits se mélangent bien avec elles, ils pourraient etre fabriqués dans une variété de formes et de tailles dont le nombre est pratiquement illimité et se plier ainsi aux différentes coutumes et traditions. Le comité est d'avis qu'un programme-pilote concerté de recherche et de développement pourrait engendrer dans la majorité des pays en voie de développement la production de matériaux mixtes convenant à des systèmes de couverture bon marché.

La plus grande difficulté à surmonter sera la mise au point de matériaux mixtes peu onéreux et qui résistent à l'action destructrice de l'humidité, des rayons ultraviolets, des insectes et des moisissures. Il faudra mettre particulièrement l'accent sur l'identification des dangers qui sont inhérents à l'emploi de produits contenant des matières plastiques. Par exemple, si la cuisine est faite sur des foyers à flamme nue, certains éléments de couverture pourraient se trouver enflammés par des étincelles et produire ainsi des fumées délétères

ou des gaz toxiques. A l'aide de techniques simples on peut traiter les polymères pour qu'ils aient une bonne tenue au feu. Mais, jusqu'à présent les applications de ces polymères traités ont été plutôt onéreuses.

Si des substances d'une bonne tenue peuvent être mises au point à un prix raisonnable, on pourra probablement transmettre sans difficulté leurs procédés de fabrication et leurs applications à tous les pays en voie de développement. La simplicité de la fabrication de matériaux de couverture à base de résines synthétiques permettrait une diffusion rapide des techniques et une commercialisation facile par les petites entreprises. Les produits finis de construction pourraient faire face à la concurrence de la tôle ondulée ou être d'un prix plus avantageux. Ces matériaux pourraient etre utilisés également dans d'autres domaines que la couverture des toits.

Le prix de revient de matériaux mixtes pour toitures pourrait être très bas. Le système serait très souple et pourrait s'adapter à une production utilisant une main-d'oeuvre importante.

Les résines et les polymères sont stables à l'état brut et peuvent ainsi être stockés pendant un certain temps, mais, pour garder leurs propriétés, ils doivent etre entreposés dans un endroit frais et à l'abri de la lumière. Du fait qu'ils se présentent à l'état concentré ils sont peu encombrants pour l'expédition et l'emmagasinage. Leur valeur intrinsèque est relativement faible tant qu'ils ne sont pas transformés en matériaux de construction. Si on ne trouve pas ces résines et ces polymères dans les pays en voie de développement, ils devront être importés. Même dans ce cas ils ne représenteront qu'une faible partie du coût total de la toiture. Pour l'importation en gros de ces résines et polymères, il n'y a pas de problème particulier de distribution—les stocks sont importants et il existe un grand nombre de fabricants. La manutention, l'emmagasinage et le transport à l'arrivée ne présentent pas de difficulté.

Les efforts de recherche sur place de ce type d'application doit comprendre une analyse couts-bénéfices des résines importées par rapport à un produit de remplacement importé tel que la tôle ondulée.

3. FAÇONNAGE DES MOUSSES DE PLASTIQUE

On devrait mettre en place un projet-pilote pour le façonnage de mousses plastiques qui puissent servir de matériaux de couverture et à cet effet mettre au point des appareils mobiles relativement petits que les pays en voie de développement soient à même de produire économiquement.

Les mousses plastiques—substances cellulaires légères produites par l'introduction de bulles de gaz dans les composants plastiques au cours de la fabrication—offrent un potentiel important en tant que matériaux souples et légers de toitures, tout en possédant une haute valeur isolante. Ces matériaux peuvent être fabriqués sur place dans une grande variété de formes et de tailles (voir annexe B). A ce jour, l'emploi des mousses plastiques a été sérieusement limité parce qu'il n'existait pas d'équipement de fabrication des mousses, simple, fiable et peu onéreux, qui soit capable de donner un produit uniforme de haute qualité.

L'équipement habituel de façonnage des mousses plastiques produit la mousse chimiquement et ensuite projette la masse écumeuse de fines bulles à l'endroit voulu. Autrefois, l'équipement de démonstration qui était utilisé sur place dans les pays en voie de développement, était complexe et fragile et exigeait un coûteux entretien. Néanmoins, les progrès récents apportés à la conception de l'équipement ont permis d'éliminer la plupart des problèmes auxquels on se heurtait auparavant. Il semblerait donc que le moment est venu de mettre à profit ces améliorations pour créer de petits appareils de façonnage de la mousse qui pourraient être fabriqués en série par les pays en voie de développement. De tels appareils, associés à une démonstration prouvant que les mousses plastiques peuvent être utilisées en combinaison avec des substances de renforcement et des enduits d'origine locale comme matériaux de couverture et de support, pourraient conduire à l'établissement profitable d'entreprises locales qui fabriqueraient non seulement l'équipement mais aussi divers produits en mousse de plastique.

Le projet-pilote recommandé devrait être organisé seulement à titre d'expérience pour permettre d'évaluer et de documenter le rendement de l'équipement, aussi bien que l'aspect économique, l'acceptation par les consommateurs, l'emploi et la durée des toitures prototypes ainsi réalisées. Le projet pourrait bien être conduit en coopération par entreprises américaines et celles des pays en voie de développement, et aussi avec la participation de centres de recherche, d'organismes professionnels orientés vers les matériaux de construction, d'organisations commerciales et avec le concours technique d'organismes s'occupant du logement.

Il est à noter que la U.S. Federal Trade Commission á récemment mis en garde les consommateurs sur le fait que les mousses de polyuréthane et de polystyrène, quand elles sont exposées au feu, peuvent offrir des risques pour leur vie ou leur santé dans certaines de leurs applications pour le logement. Ce fait est parfaitement connu des technocrates du bâtiment. Cependant, on dispose maintenant de mousses à faible production de fumée et ne permettant pas la propagation des flammes. Il est vraisemblable que de nouveaux progrès seront encore faits dans un proche avenir. Toutefois, les chercheurs qui mettent au point des plastiques moulés pour les éléments de toiture dans les pays en voie de développement, devraient être informés des dangers possibles d'incendie et tenus au courant des progrès techniques réalisés dans ce domaine.

4. SOUFRE

On devrait porter une attention particulière aux possibilités offertes par le soufre en tant qu'élément entrant dans la composition des liants pour d'autres matériaux d'origine locale, en tant qu'enduit et substance d'injection des joints et en tant que matériau à partir duquel on peut fabriquer des éléments de toiture de petite taille : les tuiles, par exemple.

Bien qu'on n'ait pas beaucoup utilisé le soufre comme matériau de construction, on devrait étudier l'étendue de ses possibilités comme liant dans les couvertures à bon marché dans les pays en voie de développement

(voir annexe C). C'est seulement au cours de la dernière décennie que l'emploi de ce matériau dans la construction a fait l'objet de recherches scientifiques approfondies. Son utilisation dans les pays en voie de développement devrait être particulièrement étudiée du fait que beaucoup de ces pays disposent de soufre en quantités importantes, soit qu'il provienne d'une activité volcanique ou du raffinage du pétrole. Le soufre peut également représenter un article d'importation peu onéreux pour les pays dont il n'est pas une ressource nationale.

Les recherches et les essais déjà faits dans ce domaine étaient principalement dirigés vers l'utilisation du soufre dans le béton—béton au soufre—et comme liant superficiel. Le soufre élément est un liant aux propriétés exceptionnelles. Il fond à 115 °C, quelques degrés à peine au dessus du point d'ébulition de l'eau. Etant insoluble à l'eau, il est ainsi imperméable à ce liquide. En emploi courant il n'a pas d'odeur et n'est pas toxique. Il est mauvais conducteur de la chaleur. Enfin, il peut être conservé indéfiniment et peut être recyclé. Toutes ces qualités en font une matière première de choix pour la couverture des toits dans les pays en voie de développement. Le soufre élément se prête particulièrement bien aux méthodes de construction utilisant une importante main-d'oeuvre. Toutefois il a certains inconvénients. Il est hautement inflammable et doit être liquéfié avant qu'on puisse y ajouter les agrégats ou la masse de remplissage. Les producteurs et les consommateurs du produit doivent être mis en garde contre les émanations possibles d'acide sulfurique en présence d'humidité et sur les conséquences dangereuses que pourait entraîner son ingestion. Les avantages semblent contrebalancer les inconvénients, cependant il est indispensable actuellement qu'un effort soit fait dans la recherche et le développement.

5. MATÉRIAUX VÉGÉTAUX CARBONISÉS

Il faudrait mettre sur pied un programme de recherche en laboratoire et d'essais pratiques sur la possibilité de transformer en plaques légères et bon marché des produits végétaux non-alimentaires et à haute teneur en amidon, carbonisés et expansés, qui ont été combinés avec des résines polyester non-saturées et les polymères connexes et qui pourraient servir pour les toitures (voir annexe G). La recherche devrait inclure des études sur place qui permettraient d'identifier le type, la quantité et l'existence dans les pays en voie de développement de produits végétaux qui pourraient servir à cet effet.

6. DÉCHETS AGRICOLES ET FORRESTIERS

On devrait établir un programme de recherche intensive sur les procédés de frabrication des résines destinées à être employées principalement comme liants à partir de produits agricoles locaux (végétaux, bagasse).

Comme on l'a noté dans l'annexe G[1], la lignine et le furfural des végétaux peuvent être utilisés sur place comme liants avec application de chaleur et en exerçant une certaine pression. Cette technique est bien connue des nations industrialisées. Il est probable que des méthodes simplifiées de fabrication permettraient aux pays en voie de développement de produire en grande quantité des panneaux de construction donnant toute satisfaction.

7. DÉCHETS DES INDUSTRIES DE BASE

Les déchets, tels que les escarbilles et le laitier de hauts-fourneaux provenant des aciéries, ont des propriétés qui leur donnent la possibilité d'être utilisés comme liants (voir annexe E). Ces déchets devraient être étudiés et ils pourraient présenter un intérêt particulier dans les pays qui ne disposent pas de ressources en calcaire et en ciment portland. Un sous-produit du raffinage de la bauxite, la boue rouge, qui est surabondante dans de nombreux pays en voie de développement, mérite également une sérieuse attention, au même titre que les déchets métalliques venant de la fabrication du fer et de l'acier. La disposition de ces déchets et d'autres résidus similaires pose un problème toujours grandissant pour l'industrie lourde du monde entier. Un double but serait atteint si on pouvait les transformer en produits utilisables. En fait, leur utilisation possible pourrait présenter un tel avantage pour les industries concernées qu'elles seraient incitées à fournir des fonds ou des matériaux pour la recherche dans ce domaine.

8. BÉTON

Un programme d'essais analytiques et en laboratoire devrait être mis sur pied pour la mise au point de produits en béton armé plus appropriés et plus économiques (voir annexe H sur le ciment armé). L'effort de recherche devrait être axé sur l'emploi de matériaux d'armature tels que le treillis métallique, la fibre de verre, la laine minérale et divers produits végétaux comme le bambou[2], l'écorce et la fibre de bois—le béton à la fibre de bois est connu sous le nom de "laine de bois" dans certaines parties du monde.[3] Une attention particulière doit aussi être apportée aux substituts du ciment portland dont certains sont énumérés à l'annexe E.

9. MATÉRIAUX À BASE D'ARGILE

On devrait établir un programme de recherche sur les méthodes destinées à améliorer le rendement et le champ d'application des matériaux pour toitures à base d'argile. (Voir annexe I.)

10. FIBRES

L'industrie textile et les autres industries apparentées utilisent des matières premières telles que le jute, le sisal, le chanvre et le coton qu'on trouve communément dans les pays en voie de développement. Il serait donc intéressant de rechercher si les déchets provenant de ces industries peuvent être utilisés en mélange dans un matériau mixte pour des éléments de toiture et quelle en serait l'efficacité.

En conclusion, le comité consultatif est d'avis qu'il existe de nombreuses voies à explorer et qu'il faudrait les mettre à profit dans les circonstances présentes.

1. INTRODUCTION

The water store (the 'tank') accounts for a large fraction of the cost of any roofwater harvesting system. Most poor households cannot afford to buy as large a tank as their roof catchment area might justify. There is therefore a strong incentive to seek cheaper yet adequate forms of tank.

The cost of a tank depends upon its size, the type and quantity of materials used in its construction, the labour needed to build it and in some areas the 'hire' of special equipment. The tank itself might be regarded as having two main parts; a water store and a set of ancillaries to lead water into and out of it (taps, an overflow, a filter, a level indicator etc.). In this paper, we restrict ourselves to considering just the water store.

Rainwater collection is in no way a new technology and is described in many publications (Gould & Nissen-Petersen, 1999; Lee & Visscher, 1992; Pacey & Cullis, 1996)In the last decade, there have been many attempts to identify better tank designs. Therefore this report starts with an analysis of needs and constraints and follows with an analysis of good existing designs. Lastly comes a description of our own work towards making tanks cheaper.

2 TANK REQUIREMENTS & CONSTRAINTS

2.1 Needs and specification

Tanks need to be watertight although some leakage (such as <5% of daily abstraction) might be tolerable if it does not weaken the structure or cause puddles. They also need to hold the required volume and to be adequately durable (say 25 years before they become unserviceable). Beyond these basic requirements we can list many further specific requirements. Tanks should:

- have a means of being charged with water without unduly disturbing tank-bottom sediments and if possible maintaining stratified flow (the bacterial quality of outlet water is maximised if the flow through the tank resembles 'pipe flow', namely 'last in is last out'
- be able to handle excess input by overflowing in a convenient and safe manner - preferably without leading water unnecessarily via the tank (such water may drop unwanted sediment in the tank)
- have a means by which the water can be extracted which is convenient for the user and which does not pollute the water left behind (as dipped buckets may)
- exclude vermin and as far as possible mosquitoes
- exclude light (so that algae do not grow and larval growth is inhibited)
- have some form of ventilation, especially if there is not an efficient filter to prevent organic material from entering the tank and decaying there
- be easy to access for cleaning (where cleaning is needed) and be unlikely to be damaged during cleaning
- have a sufficient structural safety factor to withstand wear and tear, some impacts and occasional large natural forces caused by winds and (in places) earthquakes

- not present hazards to passers-by or small children and (in some societies) offer some protection against deliberate poisoning
- not give the water a bad taste

2.2 Local constraints

There are often also local constraints upon the construction process, such as:

- absence or excessive expense of particular materials (e.g. cement, sharp clean sand)
- constraints upon the plan-area space, height or depth of a tank
- tank location; some designs are easier to locate than others

3 ROUTES TO CHEAPER TANKS

3.1 Changing To cheaper materials

Surface tanks for roofwater storage are commonly made of brick, ferrocement, concrete blocks, plastics and galvanised iron. Some of these materials are themselves variable in make-up (the cement or steel fraction within ferrocement can be varied) and all can be varied in thickness, as is discussed in the next section. Requiring a material to be both strong and waterproof considerably constrains its choice, Once however one accepts that waterproofing and structural strength can be separated and accommodated by different materials – a number of new materials options appear.

Bricks

Burned bricks are often made locally and are available much more cheaply than materials which have to be imported into an area such as plastics or cement. Tanks made from bricks can therefore be cheaper than those of "imported" materials and will also keep more of the money spent on the tank within the community. The challenge when building such tanks is to absorb the tensile stresses typical of water tank with a structure best suited to compressive forces. The Rainwater Harvesting Research Group has experimented with a number of alternatives such as external reinforcing and shaped bricks. This work is detailed in Section 7.

Stabilised soil

Another "earth technology" is to use a small amount of cement to hold together (stabilise) an otherwise soil based block. This technique can dramatically reduce the quantity of cement needed to make a tank of equivalent strength. The wet strength of stabilised soil is considerably lower than cement so the designer must either balance the cement content to ensure the wet strength is sufficient or employ some waterproof barrier to prevent water soaking into the blocks.

Rammed earth

Ramming earth between to walls ("shutters") compacting it, gives the wall a stiffness that simple soil building does not have. The technique uses only local materials and can be achieved without particularly specialised labour, it does however require some specialised tooling such as the shutters and a tamper to ram the earth into place but these can be made locally and used to make several tanks

spreading their cost. The tank wall, however, is not waterproof with this technique so a means of waterproofing the inside surface must be employed.

Wattle and daub

A traditional technique for house building in many marts of the world, wattle and daub used mud to fill in a structure made from collected roundwood. The technique is well known and practised at a village level and requires no specialised tooling or knowledge to implement. All materials are available locally and usually need only be collected, thus the only capital requirement is labour making it extremely suitable for “self help” projects.

Like all “raw” earth technologies, the technique, results in a structure that is not waterproof and so a method of holding the water must be employed. One excellent example of this is the Rwandan “tarpaulin tank” which utilises an UNHCR tarpaulin in an excavation to hold the water with a wattle and daub enclosure. This tank is further described in Section 6.

Plastics sheeting

Plastic sheeting is becoming available in many parts of the world and can be used for lining otherwise permeable tanks to render them waterproof. At a basic level this could be simple polythene sheet but this tends to have a short lifespan. There are also several fibre reinforced plastic sheets such as those used for tarpaulins becoming available in centres and also in areas of specialised demand. At present it is unlikely that these materials will shortly become widely available due to a lack of demand but appropriate promotion/dissemination could change this situation.

Waterproof coatings

Waterproof paints are quite common in the developed world where they are used to seal ponds, swimming pools etc. these paints are available in some LDC centres and local variants may be developed. Quality control will become a major issue for these to be used as any uncoated sections could result in dangerous catastrophic failure of the tank.

3.2 Minimising the volume of materials used

A second method of cost reduction is by reducing material quantities. In general we can save materials by four approaches, namely:

- removing material where it is not needed
- reducing overall material use by reducing safety factors if they are unnecessarily high
- making use of some existing structure (e.g. the wall of a house or the ground itself)
- adopting a more efficient shape whereby overall tank wall thickness can be reduced

Removing material

The first of these approaches is sometimes prevented by practicalities. Wall thickness is often dictated not by strength but by buildability. For example the upper part of the walls of a cylindrical tank are subject to lower pressure than the bottom and so theoretically could be thinner. Unfortunately it is impractical to taper bricks or even ferrocement as one builds up the wall. the. It is, however possible to go some way toward this ideal.

- If coiled wire reinforcing is used, the spacing can be varied from close-spaced at the bottom of a wall to wide-spaced near the top.
- Materials can be concentrated so that extra strength is provided only where actually needed; for example cement content of ferrocement or stabilised soil blocks can be varied with height above the base (using least at the top).
- Material thickness can sometimes be reduced step-wise by, for example using a double run of bricks at the bottom and reducing to a single run further up the tank.

Material savings should be balanced against the extra complexity of manufacture. All of these techniques have quality control implications and should be used only when workers are familiar with the techniques or are well supervised.

Reducing safety factors

The stresses in water tanks can be calculated and then the expected stress compared to measurable properties such as maximum tensile strength, compressive strength, change of shape under load, etc. So long as the expected stress is lower than the chosen maximum material stress (usually the tensile yield stress in the case of tanks), then the structure will not fail. In practical problems, the expected stress is multiplied by a safety factor (F_S) for a number of reasons.

- The local load may be larger than we realised (indeed our method of calculation may itself contain serious inaccuracies)
- The material may be weaker than it should have been or some of the original strength may have been lost through wear and tear
- The material will almost certainly not be homogeneous, that is it will be stronger in some places than others (this is especially true of building materials)

A safety factor of 5 is typical for a water tank made of building materials. If the safety factor is very large (say $F_S = 15$) then material is being wasted and savings can be made.

Few practitioners of DRWH in developing countries include a well-considered safety factor in tank design calculations. The safety factor is usually applied to tanks in one of two ways:

- by arbitrary application during design, usually leading to excessive wall thickness as the engineer errs on the side of caution
- by trial and error leading to many trials and many errors

Arbitrary application can be expensive in terms of materials, while trial and error is expensive in terms of broken tanks (and even downright dangerous if field trials use consumer tanks).

Defining a sensible safety factor can be difficult given the extreme variations in quality of materials and workmanship in developing countries. The normal engineering approach to safety factor application is to use standard engineering materials (of more or less known strength) and to look up the appropriate safety factor in an engineering data book or approved ‘code of practice’. The nature of tank construction in LDC’s is however such that ‘standard’ (well-quantified) civil engineering materials are rarely available. Sand and aggregates as found in the local village and cement itself is often of dubious quality. Reinforcement may be of poor quality and the strength of bricks fired in a clamp kiln will vary from one to another. Safety factors will therefore vary depending on the type and variability of the material used and the level of skill available to build the tank.. Some suggested Factors of Safety are in Table 1

Table 1: Factors of Safety

Material	Skill level	Factor of safety
Ferrocement	High	2-3
	Medium	4-5
	Low	7-8
Burned Brick	High	3-5
	Medium	6-8
	Low	9-12
Galvanised Iron	High	1.2-1.4
	Medium	1.5-1.8
	Low	1.9-2.3

Architectural integration

The third approach, of saving costs by integrating a rainwater tank with a house structure, has been discussed from time to time but rarely found to yield decisive economies. For space or aesthetic reasons, tanks have often been located within a house's structure (especially where the house is multi-storey) but it is hard to show that any significant material saving has been so obtained. A shallow tank with a large area may substitute for part of a roof, however the requirement that the tank's top be *lower* than the bulk of the roof from which it is supplied restricts this substitution to say veranda roofing or between stories of a multi-story dwelling. The volume of the tank is also limited by the structural integrity of the roof supports as $1m^2$ of water weighs in at one tonne!

Conversely a very tall tank might substitute for walling. This has been proposed by ??? for Australian houses (ref?) but the architectural detail of moving from normal to tank walling and back again is complex and the long, flat wall will be subject to large bending stresses. Moreover a deep, thin tank has a poor ratio of volume to wall area and may also be difficult to clean. A tank could be made as a core round which a house could be built, in the same way as some traditional village houses in India were built around grain stores. All in-house tanks, however have the problem of ensuring that tank overflow will never inundate the house – as often happens with roofs having 'internal' gullies. Any leakage from these tanks will also enter the house.

Finally tanks can be built into the basements of houses saving space and integrating the tank and house foundations. Laurie Baker has used this technique extensively in his design of The Centre for Development Studies in Karalla India albeit for non-drinking water purposes. If this strategy is to be used, account must be taken of the fact that even ground floor floors will have to be suspended and water will need to be pumped from the storage.

Optimal tank shape

Since the shape of a tank affects both the volume-to-surface ratio and the distribution of forces, it is worth examining the effect of tank shape upon material requirement. As always these material savings must be balanced against the additional complexity in manufacture, straight sides are much easier to form than curves and can be produced with a larger selection of materials. Table 2 shows a summary of tank shape from the viewpoint of induced stress, material use and construction. Three common tank shapes are considered: the cuboid, the cylinder and the doubly curved 'Thai' water jar shape.

Table 2: Relative merits of some common tank shapes

Tank shape or type		Stresses	Material usage	Construction
Cuboid		Stresses are unevenly distributed around the structure. Bending stresses are especially high near the edges.	The ratio between material usage and storage capacity is higher than for a cylindrical or doubly curved tank.	Construction is quite simple using most materials
Cylindrical		Stresses are more evenly distributed with bending stresses only near the bottom	There is an improvement in the material use to storage capacity ratio (a saving of 7.5% over a similarly proportioned cuboid)	Construction becomes more difficult with some materials e.g. bricks, but the shape is well suited to construction with materials that can be bent e.g. ferrocement and GI sheeting or built in sections
Doubly curved tanks (e.g. Thai Jar)		Stresses are well distributed. The base of the tank is of smaller diameter, reducing both hoop stresses and bending stresses there.	Material usage to capacity ratio is very good (savings of up to 20% over a cuboid)	Construction can be difficult, often relying on specialised moulds. Materials must be pliable and able to curve in two directions e.g. ferrocement and clay

The table shows that the cuboid shape fares relatively badly in terms of material use versus storage capacity and it is also associated with high peak stresses. The cylindrical shape deals quite well with stresses in comparison, and it has a lower (better) ratio of walling material to storage volume. It is still easy to manufacture, a technique well suited to circular or irregular forms. The 'Thai' style tank has the ideal shape to cope with the main induced stresses but requires greater skill and tooling to make.

Underground tanks

Significant material savings can be made if the tank is built underground. If the soil is suitable it can take the weight of the water and the walls can be made considerably thinner as they will simply be used as a waterproof layer stopping the water seeping into the soil. The geometry can also be very efficient (hemispherical) as the ground will act as a former for construction and the tank needn't stand up on its base like an above ground tank. This material advantage should be balanced against the additional cost of digging a hole (which can be significant if the ground is particularly hard) and the possibility of the tank becoming contaminated by leaks or a rising water table floating the tank out of the ground.

3.3 Minimising labour and equipment costs

Generally labour costs rise as equipment costs are reduced and *vice versa*, so one should seek to get the best balance. What that balance is clearly depends upon location. In rural Africa digging deep pits by hand is cheapest, in urban Asia it would often be possible and cheaper to hire a back-hoe for the

job. Similarly the transport of 'centrally' produced tanks or jars by motor vehicle might incur only modest costs in an urban area but quite excessive ones in a hilly rural area with few roads.

Employing moulds to build tanks improves their accuracy (and thereby may save materials) and also saves labour by reducing 'setting out' times. Moulds themselves become cheaper (per tank) if they are durable and can be used many times. Recycling moulds however requires suitable organisation – such as their attachment to a multi-system programme or availability for hire – and easy transportability.

In many cases, organisations assisting the construction of RWH systems have as their major objective the creation of income-earning opportunities in a specific locality. In consequence they seek to minimise the capital requirement associated with use of complex or motorised equipment, and to maximise the labour fraction of total costs. This approach may or may not minimise overall RWH tank costs.

3.4 Appropriate sizing

One of the simplest ways to make a tank cheaper is simply to make it smaller. Figure 1 shows the water demand satisfied by a tank compared to its size. As can be seen economics of tanks are such that the benefit of a tank is not strictly proportional to its size. The reason for this is that a smaller tank will be filled and emptied (cycled) often whereas a larger tank will only be cycled rarely. A fuller discussion of this is found in section 5

Figure 1: Benefits of tank sizing

Thus, while a large tank may be beyond the affordability of a household, a smaller tank will usually provide significant time-savings, particularly during the rainy season when footing can be wet and slippery. Another tank may also be added later and the total system capacity grown this way. This modular approach has can be seen in many parts of Southeast Asia.

3.5 Mass production

Tanks (particularly smaller tanks) benefit from the economies of scale that come with mass-production. In Thailand, a country that has undergone a massive rainwater harvesting promotion

programme, 400 litre jars are produced for less than $US5. Another possibility is the mass production of some parts portion of a tank such a the lining and this way reducing the overall complexity of tank construction and allowing local materials and skills to fill in the balance.

4 STRUCTURAL STRENGTH & STRUCTURAL FAILURE OF TANKS

In a famous case over 150 years ago, the engineer Stephenson (who had no means of analysing structures) designed an early railway bridge by a careful series of experiments on a scale model. He built the model rather weak then loaded it until it collapsed. He then strengthened the part that broke first and repeated the procedure several times. By the end of the process the bridge had increased in weight by 50% but was 6 times stronger. We might use this technique to develop more materials-efficient tanks. Unfortunately the process would be long, expensive and perhaps unreliable (since testing long-term durability is harder for tanks than for steel bridges). Moreover today we have a much better (although incomplete) understanding of theory behind the structure of a tank.

4.1 Failure modes

There are number of possible modes of structural failure for a water jar or cistern, of which the most common are:

- Cracking and leaking (which may be temporarily repairable but often later progresses to failure)
- Leaning over, due to inadequate foundations
- Bursting (which can be dangerous, with fragments flying some distance)

It is a normal pattern that when a product like a RWH tank is first introduced to a new location a very ‘conservative’ design is used. It is in consequence expensive and may need subsidy. It should be the aim of any such programme to use the period of subsidy to simplify or cheapen the product by some degree of trial and error. Unfortunately failures resulting from a practical search for the design limits are embarrassing and can lead to mistrust of the product. For this reason it is prudent to perform such experiments in private (‘behind a hedge’) at least until the probability of failure appears low. Moreover the design should be chosen to exhibit functional failure such as leaking before any dangerous failure such as bursting.

4.2 Stresses due to the stored water

Pressure forces

Water exerts a pressure proportional to its depth equivalent to 10 kPa. Per meter. The pressure always applies a force perpendicular to the inside surface of the tank, so at the bottom it acts downwards, over most of the walls it acts outwards and near the top of a doubly curved tank it can even act upwards (see Figure 2)

Figure 2: Action of pressure in a water tank

a. Straight sided

b. Doubly curved

Generally this pressure puts the tank walls into tension (stretch). This is unfortunate because many materials traditionally used for building and transferred to tank construction are only 10% or 20% as strong in tension as they are in compression.

Stresses in cylindrical tanks

In the case of a simple cylinder, the tensile stress acts around the cylinder and is called “hoop stress”. This stress can be found using the equation:

$$\sigma_h = \frac{p\,r}{t} \tag{1}$$

Where:

σ_h is the hoop stress

p is the water pressure

r is the tank radius

t is the wall thickness

This simple result however is only true when the walls of the tank are free to move as shown in Figure 3a. The movement is only very small and can be achieved by using a flexible material between floor and wall such as bitumen or by allowing the wall to slide along the floor. Where the walls are fixed, such as at the base of a tank, they will tend to bow out as shown in Figure 3b

Figure 3: Movement of tank walls due to pressure

a. Unconstrained

a. Constrained

This will change the hoop stress and also cause two other stresses acting in different directions as are shown in Figure 4.

Figure 4: Stresses caused by constrained walls

a. Shear Stress

b. Bending stress

The wall will be stressed in shear at its edge where the water pressure forces it outwards but the base opposes this: the shear stress acts through the wall in a horizontal plane (Figure 4a). Another stress is due to bending of the tank walls as they bow outwards. This is especially high near the joint and will cause vertical compression of its outside face and tension on the inside face of a tank (Figure 4b) both acting vertically up the wall which can cause cracking of the inside face leading to failure.

Quantifying this situation is rather more complex and uses the technique of shell theory where the tank walls are idealised as being very thin (like egg shells). The theory also breaks the problem down into two parts. The first part considers the wall to be very flexible and therefore incapable of being stressed in bending or shear. The second part looks at the bending only and is confined to the boundaries between the wall and the floor where these forces are most prevalent. Furthermore the tank is considered to be made of a material whose properties are constant throughout and which will deform in direct proportion to the forces acting on it (Hooke's law). The relevant equations (Flugge, 1967) are:

$$N_\theta = \gamma r\left(h - x - he^{\frac{-\lambda x}{r}}\cos\frac{\lambda x}{r} + \left(\frac{r}{\lambda} - h\right)e^{\frac{-\lambda x}{r}}\sin\frac{\lambda x}{r}\right) \tag{2}$$

$$M_x = -\frac{\gamma r t}{\sqrt{12\left(1-v^2\right)}}\left(\left(\frac{r}{\lambda} - h\right)e^{\frac{-\lambda x}{r}}\cos\frac{\lambda x}{r} + he^{\frac{-\lambda x}{r}}\sin\frac{\lambda x}{r}\right) \tag{3}$$

$$Q_x = \frac{\gamma t \lambda}{\sqrt{12\left(1-v^2\right)}}\left(\left(\frac{r}{\lambda} - 2h\right)e^{\frac{-\lambda x}{r}}\cos\frac{\lambda x}{r} + \frac{r}{\lambda}e^{\frac{-\lambda x}{r}}\sin\frac{\lambda x}{r}\right) \tag{4}$$

where:

N_θ is the radial hoop force

M_x is the bending moment

Q_x is the shear force

γ is the specific weight of water (density times gravity)

r is the radius

h is the height water height

x is the height of the stress to be calculated

v is poisons ratio (the ratio of a materials change in shape in the direction of a stress to the change in shape perpendicular to the stress – as a rubber band is stretched it gets thinner)

λ is given by

$$\sqrt[4]{3\left(1-v^2\right)\left(\frac{r}{t}\right)^2} \qquad (5)$$

These fairly daunting equations can be easily coded into a spreadsheet and used to provide useful curves for designing tanks. Typical output is shown in Figure 5

Figure 5: Stress curves for cylindrical tank with fixed base

a. Hoop stress b. Bending stress c. Shear stress

Design considerations

Design to resist tensile stresses, whether vertical due to bending, radial hoop stresses and shear stresses acting through the wall, obviously includes the use of adequate wall thickness and adequate material tensile strength. It is sometimes assumed that brick and concrete cannot carry *any* tensile stresses without failing, but this is not so. Although it may be prudent to include steel reinforcing in a tank wall to prevent dangerous bursting, it is uneconomic to include so much that the mortar or brick carries negligible tension. If one relied solely on the stiffness of the reinforcing, its movement under water-pressure would almost certainly result in cracking of the mortar or brick matrix, causing perhaps leakage and almost certainly rusting of the reinforcing. Reinforcement that passes from a base into the bottom of a tank's walls will help resist both shear and bending stresses. Extra wall thickness, or filleting at the joint between wall and base is also a useful strategy.

4.3 Stresses due to materials shrinkage

As well as the cyclic stresses due to the water rising and falling inside the tank, there are other stresses due to the material *shrinking* during construction. Cement mortar, concrete and stabilised soil all shrink slightly (about 1 part in 1000) as they cure or dry out. If mortar or other such material is restrained during curing - for example by a metal mould or by attachment to a base - there will be a struggle between the mortar trying to shrink and the constraint trying to stop it. In consequence large stresses can develop in the mortar causing it to crack. To reduce such shrinkage cracking, we could:

- Remove stiff constraints (e.g. putting lime mortar or a rubber strip between the wall bottom and the base plate or using flexible moulds);
- Reduce mortar shrinkage by using a very dry mortar mix or a low cement content: unfortunately the former makes the mix difficult to work and the latter reduces strength;
- In the case of soil, use a low clay content;
- Spread such cracks that form (so that there are many tiny cracks rather than one big one) by putting a metal or fibre mesh inside the mortar: this is particularly helpful in controlling leakage since splitting one wide crack into two narrow ones will reduce leakage flow about 4-fold;

- Choose a shape (e.g. a sphere) where there are no hard attachment constraints;
- Modify the material by the addition of a slightly expansive component that counteracts the normal shrinkage;
- In the case of a render applied only to achieve water-tightness, it is often possible to apply it in two layers and place a sealant such as cement-plus-water between the layers.

5 ECONOMICS OF TANK SIZING

5.1 Economic overview

All households already have some access to water from point sources. For some days per year, many also employ 'informal' rainwater harvesting, placing bowls and jugs under eaves or even trees during rainfall.

The introduction of more formal (and productive) RWH will normally be accompanied by three benefits. The most obvious is a reduction in the time spent carrying water from point sources – a reduction more or less proportional to the volume of water no longer carried. The second is an increase in household water consumption wherever it was previously constrained by the effort of collection. The third is a common, although not invariable, increase in water quality. All these benefits rise with DRWH storage capacity, albeit in a way showing diminishing returns.

The increase in water consumption with RWH has not been widely measured. Generally any increase is restricted to the wet seasons. DRWH is not generally capable in the dry seasons of supplying quantities larger than already obtained from point sources: this means that it will be used to supplement, but not to substitute point-source water.

The costs of DRWH are overwhelmingly capital costs, as neither operation nor maintenance usually involves significant expenditure. These capital costs are subject to economies of scale. The sensitivity (elasticity) of tank cost to storage capacity is about 0.6

5.2 Value of water

As with many other goods, water has a declining value with quantity. The first litre per day is worth more than the tenth. By examining the limited data available that relates household consumption per day to the effective unit cost of water (i.e. cost per litre), we might construct a curve such as shown in Figure 6. Each socio-economic group would have its own curve.

The cost line on 6 is horizontal, which reasonably represents the situation where water is fetched, each successive litre requiring the same input of labour. Such a line does not fairly represent harvested roofwater, where the effective cost general rises with daily consumption despite the economies of scale in tank construction. A typical cost v volume characteristic for RWH supply is shown in Figure 7.

Figure 6: value vs. quantity

Figure 7: cost vs. volume

Sometimes we can find examples of water purchase and use them to infer the value of water. Richer households, or those experiencing illness, may pay for water to be brought to the house. More usually we have to infer costs indirectly through conversion of fetching distance/height into time and then time into money. Such costs, like the value of water discussed above, will be lower for poorer households than for richer ones.

5.3 Combining RWH with other water sources

For a given size and location of RWH system and for a given operating strategy, there will be a limit on the water it can supply per day, per week or per year. The maximum per year, corresponding to zero tank overflow, in litres will be the product of roof area (m^2), the annual rainfall (mm) and a run-off / capture factor (typically 0.85).

Consider first the situation where we can disregard seasonal factors, and assume that before RWH arrived, daily consumption from a point source was Q_P (litres/day). Q_P is determined by the interaction of the user's demand (cost v volume) curve and the unit cost C_P of supply from the point source. The daily cost to the user was therefore Q_P x C_P.

Figure 8: Value of rainwater

If the water Q_R available per day from RWH is *less* than Q_P, then the users will draw Q_R from the RW system and the remainder Q_P-Q_R from the point source. The total consumption will not increase and the effective value of the harvested rainwater will be the saving Q_R x C_P .

If the water Q_R available per day from RWH is *more* than Q_P, then the users will increase their consumption from Q_P to Q_R and the rainwater will be worth more than the former total cost Q_P x C_P. Exactly how much more will depend on the user's demand curve. The situation is represented in the diagram below, where Area (i) is the saving (Q_P x C_P) while Area (ii) is the value of the extra water.

Note that Q_R is the daily amount *available* from RWH, whereas Q_P is determined by the price of supply (from non-RWH sources). The total value Area(i) + Area(ii)) is less than (Q_R x C_P) because the extra water is per litre less valuable to the user than the water 'replaced'.

5.4 Seasonal effects and water management strategies

In the last section we ignored seasonal effects, although one can identify the condition $Q_R<Q_P$ as representing a dry season and $Q_R>Q_P$ as representing a wet one. However seasonality is central to the operation and performance of a RWH system. A user can choose to emphasise dry season security or alternatively to emphasise roofwater capture. To some extent the dry and wet season water needs are in competition with each other. Consider the following four water management strategies for an already built RWH system.

To make the strategies easier to visualise, assume a scenario typical of a homestead in the Great Lakes region where mean daily roofwater runoff is R = 100 litres). Assume that 'dry' weeks (runoff less than 350 litres per week) comprise 1/3 of each year and that the RW storage capacity is 700 litres (7 x R or '1 week'). This storage is only modest, but corresponds to perhaps 50 days drinking water or 14 days total water under very careful management.

Strategy 1 – *High Water Capture* – Water is withdrawn at a high rate, Q = 1.5 R, (e.g. 150 litres/day under our scenario) whenever it is available. This will result in fairly low occurrence of tank overflow, but leave little reserve for dry weeks.

Strategy 2 – *High Security* – Water is withdrawn at a low rate, Q = 0.5 R, (e.g. 50 litre/day) whenever it is available. Much water will overflow the tank, so annual capture will be low.

Strategy 3 – *Adaptive* – Water is withdrawn at a rate Q determined by how much is in the tank, thus:

Q = 1.5 R (e.g. at 150 lpd) if tank > 2/3 full;

Q = R if tank < 2/3 but >1/3 full;

Q = 0.5 R, if tank < 1/3 full.

Strategy 4 – *Maximum Security* – Water is saved for the dry seasons and drawn frugally (e.g. 50 litres/day) *only* after nearby point sources have run dry or after 2 weeks without rain.

The trade-offs involved between these alternatives are summarised in the following table, in which the word 'security' is taken to mean the fraction of days the demand is met by RW (the tank does not run dry). The factor K is the dry-season value of water (valued at its cost from the nearest point source) divided by its wet season value. Thus K=1 represents places where point-source water is unvarying through the year, whereas the extreme value K=10 represents places where in the dry months all local sources dry up, so water must be queued for, then carried from, very far away. A typical value of K in the humid tropics might be 2.

Table 3 suggests how we might account for seasonal differences in our economic evaluation, namely by assigning different wet and dry season values for water and operating the system to maximise their sum.

Table 3:System Performance under Different Operating Strategies

Strategy No	Annual consumption	Relative value of annual water harvested		Wet season security	Dry season security
		if K=1	if K=10		
1	high	high	med	high	v. low
2	low	med	med	high	low
3	medium	low	v. low	high	low
4	very low	med	med	nil	med

Table 4 represent the simulation of the four strategies applied to respectively a small DRWH system (storage volume V = 7 x mean daily run-off, R), a medium size system (V/R = 21) and a large system (V/R = 63). Daily rainfall data for 10 years has been used and a roof area of 45 m^2 has been selected to give the assumed mean run-off R = 100 litres/day. For Mbarara, the town used, the dry season (defined by rain in the last fortnight being under 50% of mean fortnightly rainfall) is 36% of the year.

Table 4: Relating RWH system performance to operating strategy and storage volume

Strategy number / type	V/R	Capture Efficiency	Tank Utilisation	Mean daily consumption Q in litres		'Security' (*S*) = fraction of days demand is satisfied by roofwater		
	tank size days	*E*	*U*	Q_1 *K*=1	Q_5 *K*=5	S_w Wet	S_d Dry	All year
Small tank,								
1 High demand High capture	7	**0.70**[1]	36.5	70	**95**	0.75	**0.22**	0.56
2 Low demand High security	7	**0.41**[3]	21.4	41	**80**	na	**na**	na
3 Adaptive	7	**0.66**[2]	34.4	66	**93**	0.94	**0.38**	0.74
4 Max security in dry seas	7	**0.17**[4]	8.9	17	**84**	na	**0.52**	na
Medium size tank								
1	21	**0.91**	15.8	91	**125**	0.90	**0.25**	0.67
2	21	**0.47**	8.2	47	**107**	na	**na**	na
3	21	**0.86**	14.9	86	**138**	1.00	**0.66**	0.88
4	21	**0.26**	4.5	26	**128**	na	**0.73**	na
Large tank								
1	63	**1.00**[1=]	5.8	100	**165**	0.92	**0.38**	0.72
2	63	**0.51**[3]	3.0	51	**123**	na	**na**	na
3	63	**0.99**[1=]	5.7	99	**203**	1.00	**0.98**	0.99
4	63	**0.37**[4]	2.1	37	**182**	na	**1.00**	na

Notes:
1. Data is for Mbarara, Uganda
2. Annual run-off = annual demand
3. na indicates strategy does not allow demand to be met.
4. Highlighted cells indicate best strategy or within 3% of best
5. Strategy 1 gives best $\mathbf{Q_1}$ (highest water capture)
6. Strategy 3 gives best $\mathbf{Q_5}$ (highest benefit if K = 5)
7. Strategy 4 gives best $\mathbf{S_d}$ (highest dry season security)
8. Strategy 3 is always best or second best by all measures.

‘Value’ is calculated assuming first litre per day is worth 1.5 falling via 0.5 at the 100th litre to zero at the 150th litre

Strategy 1 is to withdraw 1.5 times base demand when available (and otherwise what is available)

Strategy 2 is to withdraw 0.5 times base demand when available (and otherwise what is available)

Strategy 3 is to withdraw 1.5, 1 or 0.5 times base demand, according to amount in tank

Strategy 4 is to withdraw nothing in wet season and in dry season base demand when available (and otherwise what is available).As well as water supplied (column 5), a ‘weighted’ water supplied column is shown alongside in which effectively K = 5. This yields the weighting (a ‘wet season litre’ is a cost-equivalent volume): 1.0 dry season litre is deemed to be worth 5.0 ‘wet season litres’

The **bold** columns in the table contain the performance measures of most interest.

Column 3 shows ‘Capture efficiency’, (*E*) – a high value indicates that most of the roof run-off is being consumed.

Column 8 shows ‘Dry season water security’, (S_d) – the fraction of dry season that tank does not run dry and so demand has been satisfied; note however that under Strategy 1 the dry season demand is maintained very high at 1.5 *R*, whereas the other strategies are using demand of only 0.5 *R* for the dry season.

Column 6 shows weighted annual water consumption, Q_5, which is a measure that attempts to combine quantity, and security measures, by valuing wet season water much more highly than dry season water.

Examination of the top part of the table – which is for a small system with V/R only equal to 7 days – indicates that Strategy 1 (in which water is drawn generously whenever available) gives the highest annual water yield E, the lowest level of dry season security S_d, yet a high value for the seasonally-weighted yield W_e .

By contrast Strategy 4 (water is drawn sparingly and only in the dry season) gives the highest dry season security at the cost of the lowest annual yield. The seasonally-weighted yield is however also low. In fact we can dismiss Strategy 4 because even here, where per litre we have valued dry season water at *five times* wet season water, it still gives the lowest output valuation.

Strategies 2 and 3 are intermediate in performance, with Strategy 3 (adaptable) generally outperforming Strategy 2 (fixed low-demand).

From this table we can conclude that unless dry season water has exceptional value – e.g. it is per litre worth more than the 5 times wet season water assumed in the table – Strategies 1 (high usage) and 3 (adaptive) are superior to the other strategies.

The bottom band of the table is for a much more expensive system with 9 times larger storage. With such a large tank, the relative superiority of Strategy 3 is increased. We also see the benefit of the larger store. Comparing say Strategy 3 for the very large tank with that for the small one, we find a 50% increase in water harvested (E), a nearly 4-fold increase in dry season security (S_d) and under the assumed value ratio (K=5) a 120% increase in water value. Table 5 shows the variation in value of water harvested for varying values of K and for various sizes of tank. It confirms that small systems (V/R < 10 days) give a generally acceptable performance unless dry season water is deemed very much more valuable (e.g. K=5) than dry season water. Note the clear ‘diminishing returns’ with

increase in tank size. If water value had been plotted against tank *cost* rather than tank *size*, the same pattern of diminishing returns would appear but with a slightly reduced strength.

A small system in the humid tropics, attached to a 50m^2 roof, might be expected to harvest around 25,000 litres of water per year (say 75% of run-off), averaging about 90 litres per day in the wettest 8 months and 30 litres per day in the driest 4 months.

Table 5: Performance under Strategy 3 – Table showing variation of value ratio, capture efficiency and security with tank size

	dry:wet value per litre	Normalised tank size – V/R in days								
		1	3	5	7	14	21	30	60	90
Benefit ratio = value of water harvested ÷ value water demanded	if K=1	0.29	0.49	0.60	**0.66**	0.79	0.86	0.91	0.98	1.00
	if K=2	0.24	0.40	0.49	**0.53**	0.65	0.72	0.79	0.90	0.94
	if K=5	0.18	0.30	0.35	**0.38**	0.48	0.56	0.65	0.82	0.88
Capture efficiency		0.39	0.66	0.76	**0.82**	0.90	0.93	0.95	0.99	1.00
Security		0.15	0.41	0.57	**0.67**	0.81	0.86	0.90	0.98	1.00

Notes:
1. Under this strategy the demand is varied from 0.5 to 1.5 times the mean daily runoff according to how much water remains in the tank
2. V/R is tank size (normalised to mean daily run-off); K is dry-to-wet season water value ratio; the bold column shows the performance of a typical very-low-cost RWH system

6 ANALYSIS OF EXISTING TANK DESIGNS

In the course of the project a number of tank designs have been investigated by the RHRG. These have been written up as "case studies" and are available on the project web site at:

www.eng.warwick.ac.uk/dtu/rainwaterharvesting/casestudies.htm.

A summary of these designs is set out below

6.1 The Pumpkin Tank, Sri Lanka

The Sri Lankan Pumpkin Tank, and the associated construction technique, was developed as part of a World Bank sponsored Water and Sanitation Programme that was implemented in the country

between 1995 and 1998. The Community Water Supply and Sanitation Programme (CWSSP) covered 3 districts within the country – Badulla, Ratnapura and Matara Districts. Hundreds of these tanks have been built in areas where conventional supply schemes, such as piped supplies or groundwater supplies, were difficult to provide.

Catchment (typical) – 32m^2

Storage – 5 – 7 m^3

Storage cost - £112 (skilled labour - £19, Unskilled, £21 unskilled)

Material - ferrocement

Lessons

- Doubly curved structures
  - Material economies
  - Specialised techniques needed
  - Ferrocement construction
  - Use of mould for many tanks

6.2 Underground brick dome tank, Sri Lanka

This is another RWH system which was developed by the CWSSP programme in Sri Lanka. The tank, a 5m^3 underground brick built tank.

Catchment – 28m^2

Storage – 5m^3

Storage cost - £125 (skilled labour - £15, Unskilled, £28 unskilled)

Material - Brick

Lessons

- Brick tank construction
  - Less skilled
  - *but* used as much cement as pumpkin tank

- Brick dome roof
- Low cost pumps for water extraction

6.3 Brick built storage tank, Sri Lanka

This is an example of local initiative in design and manufacture in DRWH. The tank in question was constructed in the village of Ahaspokuna, near Kandy, in the highlands area of Sri Lanka. The tank was built 10 years ago by a local mason for the Rajasomasari family and has since been copied so that there are now several of these tanks in the area.

Catchment – 90m^2

Storage – 3m^3

Storage cost - £80 (est.)

Material – Brick with cement render

Lessons

- Square construction
  - Good for bricks
  - Simple for local labour

6.4 Partially below ground brick built tank, Sri Lanka

This tank was built by Mr G. Victor A. Goonetilleke in the hill town of Kandy,. Mr Goonetilleke decided to build his RWH tank after experiencing difficulty in sinking a well to sufficient depth to have a reliable perennial source of groundwater at the site of his newly built home.

Storage – 10m^3

Storage cost - £550

Material – Brick with cement render

Lessons

3 Partially below ground construction – many of the advantages of below ground construction but with several of the advantages of above ground construction

6.5 Underground storage cistern – 4 to 10 cubic metres, Uganda

This tank (or cistern) was developed in Uganda by members of the Development Technology Unit, Warwick University and members of the Uganda Rural Development and Training Programme (URDT), between 1995 and 1997. Work is still continuing on the refinement of the tank. URDT is a service NGO located at Kagadi in Mid-Western Uganda. Several of these cisterns were built and tested with the aim of developing a low cost (under US$150), alley, domestic, water storage technology for the surrounding region.

Catchment – Varying

Storage – 4-10m^3

Storage cost – £90 (8m^3)

Material – Cement Mortar

Lessons

- Underground tanks – very thin walls are possible in appropriate soil
- Unreinforced mortar dome roof – lower cost due to no steel
- Ground as formwork – reduced cost amortisation of formwork

6.6 Ferrocement water tank using former

Used for many years in parts of Africa these tanks have been designed to be as simple as possible to build in self-help programmes. The users, who are at first unskilled in this sort of construction, can contribute their time and efforts in collecting sand and water, digging the foundations and preparing the mortar under the general guidance of a trained builder. With experience they quickly learn how to make the tanks without further guidance. A trained builder with 5 helpers takes approximately 3 days to complete the tank. The users often contribute some money towards the cost of the tank, which helps to cover the builders' wages, the cement, reinforcement and the hire of the corrugated iron formwork

Catchment – Varying

Storage – 10m^3

Storage cost – £90 (8m^3)

Material – Ferrocement

Lessons

- Reusable formwork with built-in depth gauge (corrugations)
- Adapted from successful commercial design from New Zealand
- Wire reinforcement graded through structure (more on bottom)
- Reinforcing from base to walls and filleted base join to avoid cracking at base

6.7 RWH in the barrios of Tegucigalpa, Honduras

Health statistics show that the residents of the barrios are suffering from a number of water related diseases that could easily be avoided with provision of a reliable, clean water supply. Unfortunately, more than 150,000 residents have to find their own water. Although technically unsophisticated and

lacking some good health practice, the systems show what urban settlement have done to improve their own lot. Many of the systems make use of recycled or scavenged materials and some examples show high levels of initiative.

Storage – 0.2m^3 used barrels (up to 3) or 1-2m^3 open concrete tanks

Storage cost – £10 (drum) - £18 “small tank

Material – Steel drum or plastered bricks

Lessons

- Impact of very small storage
- Use of available containers

6.8 Tai Jar

This type of water vessel was originally developed for a large country wide programme in Thailand that has installed over 10 million jars. Small jar making became a successful business with many companies producing up to 30 jars a day. The design has also been adopted in East Africa and South Asia

Storage – 0.5-2m^3

Storage cost – £ 30 for a 2m^3 jar

Material – Pottery or cement

Lessons

- Small tanks used modularly – several houses have more than one and up to 10 are used commercially
- Mass production – lead to much cheaper tanks
- Critical mass – the programme grew exponentially and became self sustaining within a few years

6.9 Plastic Lined tanks

Several experiments have been done using plastic sheets as a waterproof membrane in an otherwise wholly traditional structure. The bamboo tank developed by ARTI in Pune India uses a polythene sheet in a basket structure that is traditionally used for grain storage. In East Africa Rwandan refugees have used a tarpaulin distributed by UNHCR as a liner for an underground tank over which a wattle and daub enclosure is built to protect the water.

Lessons

- Small, portable imported input bolstering principally local technique – greatly reduced cost
- Some questions of durability

6.10 Summary

Table 6: Summary analysis of case study material

	Material costs	Percent Labour costs	Unit costs (per m^3)	Skills required	Equipment/ tools required	Space requirement	Suitability for incremental adoption	Reliability	Water quality, safety and health	Impact on insect breeding	Stage of maturity or experience

7 RHRG RESEARCH INTO MEANS OF REDUCING TANK COSTS

7.1 Research strategy

Having collected information on existing rainwater systems and identified probable areas for design improvement, the RHRG has developed several cheaper tanks, concentrating on materials substitution and material reduction while working mainly with smaller tanks suitable for incremental adoption. The main materials investigated have been:

- Rammed Earth
- Stabilised soil blocks
- Bricks
- Plastic linings

Various underground tanks have also been developed mainly on the partly below ground model. A lift-on tank cover has also been developed to remove the need for formwork from the cover making process.

7.2 Use of externally reinforced bricks

Brick is a material that is used widely in developing countries and is thus readily available. It is ideally suited to wall construction, but not quite so well suited to conventional larger volume tank construction. As it;

- has a poor strength in tension
- has a poor adhesion one brick to another through the mortar and so tensile forces must be spread through the brick runs which will be in sheer with one another
- can need more cement than an equivalent Ferrocement tank due to poorly fitting bricks

One way of improving the suitability of brick to low cost tank manufacture is by using external steel reinforcing to give additional hoop strength to cylindrical brick tanks. If an empty circular tank is wound with steel reinforcing wire on the outside, and the wire is then tightened, we will achieve 'post tensioning' whereby the masonry (brick/concrete) is initially in compression and the steel in tension. Putting the steel on the outside not only facilitates the post-tensioning but also makes it easier to protect the steel from being rusted by seepage from inside the tank. Filling the tank with water will

result in a lowering of the compressive stress and strain in the mortar and an increase in the tensile stress and strain in the steel. One such tank has been built and was detailed in Milestone Report A2

The technique holds some promise as it is easy to implement, however there is some doubt over the availability of tensioning tape as described in the report. It should, however be possible to use galvanised wire for this purpose although more will be necessary due to its lower tensile strength.

Table 7: Pros and cons of brick tanks

Pros	Cons
• low material cost • suitable material readily accessible locally in many parts of the world • a well-known and widely-used technology in many parts of the world • a simple technology that is easily taught to semi-skilled people	• not ideal for round tanks as extra mortar or special angled bricks are needed • Poor in tension – Needs reinforcing or very thick walls

7.3 Use of rammed earth

The use of rammed earth has been the subject of a previous report to the EU (Milestone A5: *Stabilised Soil Tanks for Rainwater Storage*, submitted September 2000) so only a brief summary will be presented here.

Rammed earth is a technique which is experiencing a resurgence of interest, particularly in developing countries where cement is expensive and in “green” architecture where its low energy use and excellent thermal properties are particularly appreciated. The technique has been used for centuries for the construction of houses many of which are still standing, attesting to its stability and longevity.

Just as it’s name suggests this technique involves earth being rammed between two shutters, using a rammer or tamp. The shuttering is removed to reveal the wall. Walls are usually constructed in sections of a few feet long by a foot or two deep with shuttering moved along to form a continuous wall. The shuttering is then raised and placed on top of the first ‘lift’ to construct the subsequent ‘lifts’.

Several experiments with rammed Earth have been undertaken by the RHRG both in the lab and in the field. The material has proved capable of withstanding the forces typical of a tank however there are some practical problems. The pros and cons of Rammed earth tank construction are listed in table

Table 8: Pros and cons of rammed earth tanks

Pros	Cons
• very low material cost • suitable material readily accessible locally in many parts of the world • a well-known and widely-used technology in many parts of the world • a simple technology that is easily taught to semi-skilled people	• not suitable for below-ground tanks or cisterns • in the case of leaks serious problems can develop, especially if unstabilised earth is used • high labour input

The main problem with rammed earth is its wet strength. The tank must be fitted with a waterproof lining to hold the water. If this liner becomes damaged and *any* water leaks, then the tank will almost certainly fail as any water ingress will ultimately seep out along with some soil, this process is continued until a hole forms ultimately growing large enough to destroy the tank's structural integrity.

7.4 Use of stabilised-soil

Stabilised soil has also been covered in a previous report (Milestone A5: *Stabilised Soil Tanks for Rainwater Storage*, submitted September 2000)

Stabilised, compacted, soil block technology involves compacting a suitable soil, which is often mixed with a small percentage (typically 5 – 10%) of cement, using a manual or hydraulically assisted ram or press. This compaction reduces the voids in the material and hence it susceptibility to attack from water. Special moulds can be manufactured to produce blocks of different shapes for special purposes.

Work has been carried out on stabilised soil blocks for tank construction in two locations (Uganda and Sri Lanka) In the case of the cylindrical tanks manufactured in Uganda, curved blocks were produced. For a cylindrical above-ground tank. In Sri Lanka a square underground tank was produced.

The Uganda work involved the building of two experimental cylindrical water tanks in collaboration with Dr Moses Musaazi, a lecturer at Makerere University. Both were built above ground of curved stabilised-soil blocks with end interlocking, 280mm x 140mm x 110mm high, made with an Approtec

(Kenyan) manual block press. The soil used was a red somewhat pozzolanic local soil previously known to make strong blocks. The tanks were built on concrete plinths, lined with 'waterproofed' mortar (3 parts sand, 1 part cement and .02 parts 'Leak Seal' waterproofing compound). There was no metal reinforcing.

Tank 1 was 2m high, with an internal diameter 1.3m, wall thickness 140mm (+ 15mm render) and used blocks incorporating 6% cement. It has been filled with water and briefly withstood a maximum head of 2.m at the wall bottom before failing catastrophically (and spectacularly). 2, for test purposes, has been built to 5m high, has internal diameter 1.0m and the same wall thickness, but with only 3% cement. It has been filled with water and therefore withstood a head of 5.0m at the wall bottom. The inconsistency of the result could be attributed to an undersupply of cement to the blocks which made up tank one resulting in a low wet strength, coupled with a cracking of the mortar used to line the tank.

The pros and cons of stabilised soil construction tank construction are listed in table 7

Table 9: Pros and cons of rammed earth tanks

Pros	Cons
• Reduced cement content resulting in inexpensive blocks •	• Low wet strength • Reduced cement content must be balanced against lower strength requiring thicker walls • Needs specialised tooling for compacted blocks • Low tensile strength of block joints

7.5 Lining tanks with plastic bags

Plastic linings can considerably reduce the cost of the tank by removing the need for any building work to be watertight. Indeed they can be simply placed in a hole to form a very cheap and portable tank (although a cover should be constructed). Plastic liners also allow removal for inspection, cleaning, maintenance and occasional repair.

Work on plastic linings by the RHRG includes the development of a technique for welding 250 micron construction or damp proof membrane (DPM) plastic sheet to make 'bags' (similar to large bin liners) that fit inside the tank structure to form a waterproof lining. The welds themselves have proved successful with the weld both watertight and stronger than the plastic itself. The technique uses simple tools and can be taught in a couple of hours to a reasonably skilled craftsperson. One skilled person should be able to make a bag in a single day and productivity can be greatly enhanced by batch production. However, while the welding technique has been successfully developed, there are still problems to be overcome in relation to the quality of 'off-the-shelf' plastic sheet and failure of the lining due to abrasion. Observations in the field suggest that plastics with a woven structure may be more resilient, however these will not weld with the technique developed at Warwick.

The availability of plastic tubes from local markets is quite wide spread and a 600litre "plastic tube tank" was also developed in the course of the project. Details of this tank can be found in DTU Technical Release *TR-RWH08 Plastic Tube Tank (600 litres) – Instructions for manufacture*. (Rees & Whitehead, 2000b)The 87cms diameter tube is the largest that was found at the time but the design could be easily modified for different sizes of tube. The tank is based on the partly below ground concept and consists of a brick parapet wall, which incorporates the inlet basin and handpump and the lower section ground excavation, lined with two plastic liners one inside the other. The tanks have developed slow leaks reducing their effectiveness but are still holding water and making a significant contribution to household water where they have been installed.

Table 10: Pros and cons of plastic linings

Pros	Cons
• Greatly reduced cost • Portable • No clambering on or in the tank is required during construction. • No curing time is required. • Can be removed for cleaning./inspection • Can be batch produced	• Fragile – likely to tear, subject to pin holes • UV degradation • Joining requires specialised techniques

7.6 Simple underground tanks in stable ground

The RHRG has also experimented with creating underground tanks using stabilised soil with bamboo reinforcing and a plastic liner for waterproofing. The work (undertaken by the Open University in Sri Lanka) .The tank was designed to contain 3600 litres of water. It is trapezoidal with 100cm x 100cm square cross-section at the top and 80cm x 80cm square cross-section at the bottom of the tank. Strips of bamboo are used both as a support to the tank walls and to protect the lining material, which is 500 gauge polythene sheet. During the development soil samples were tested for strength and durability and a 1:12 cement:soil ratio was found to be optimum with the local soil. This will, however differ with location.

The problems of covering such pits can still cause cost problems absorbing more than 2/3 of the cost of such a tank. Tanks have also been broken due to raising water table, punctured by tree roots and are vulnerable to infiltration by runoff.

Table 11: Pros and cons of simple underground structures

Pros	Cons
• Greatly reduced cost as surrounding ground gives support allowing lower wall thickness. • More difficult to empty by leaving tap on • Can be made unobtrusive	• Water extraction is more problematic – often requiring a pump • Leaks or failures are more difficult to detect • Contamination of the tank from groundwater and surface runoff • Tree roots can damage the structure • There is danger to children and small animals if tank cover is left off • Flotation or breaking of the cistern can occur if groundwater level rises

7.7 Partly-below-ground tanks

Several of the problems of underground tanks can be overcome by siting the tank partly above ground and partly below ground. These tanks have been described in Milestone Report A3. Details can also be found in the DTU Technical release *TR-RWH 01 Partially Below Ground (PBG) Tank for Rainwater Storage – Instructions for Manufacture*, (Rees, 2000b) available at: the DTU website. Over 20 of these tanks have been built in East Africa and feedback suggests that the tanks are easy to construct by masons with some training, at a reasonable cost.

Table 12: Pros and cons of Partially below-ground tanks

Pros	Cons
• Lower material requirements • Difficult to empty by leaving tap on • Reasonably unobtrusive • Surrounding ground gives support allowing thinner walls and thus reduce costs	• Requires a pump • Leaks or failures are difficult to detect • Contamination of the tank from is possible • Tree roots can damage the structure • Flotation of the cistern may occur

7.8 Lift-on tank covers

The lift on tank cover developed by the RHRG has been detailed in Milestone Report A2 and in DTU Technical Release *TR-RWH 04 – Low-cost, thin-shell, 2m diameter ferrocement tank cover - Instructions for manufacture (Rees, 2000a).* The thin-shell ferrocement tank cover is designed in such a way that it can be manufactured without the use of a mould or shuttering. It can also be manufactured remote from the tank to which it is to be fitted and moved into place once complete. The aim is to reduce the cost of the tank (cover) by eliminating costly shuttering or moulds and by reducing the quantity of material used to manufacture the cover. It also means that the cover can be removed at a later date for maintenance, refurbishment or cleaning. The cover can be manufactured by two persons (one skilled and one unskilled) in a single day (with some time required after that for curing) using tools required for the construction of a simple cylindrical ferrocement tank.

The design is based on a frame known as a reciprocal frame, that has spokes that, when loaded, put little radial loading onto the structure on which it sits. The frame is covered with a wire mesh that is then rendered with a sand cement mix.

Table 13: Pros and cons of lift on lank covers tanks

Pros	Cons
• low cost – reduced use of materials • no shuttering or mould required • strong and lightweight – the tank cover is designed to be strong (through good quality control) and light at the same time • good quality control can be achieved through easy working environment • can be manufactured by two people in a single day (one skilled and one unskilled) • no clambering on top of tanks required during construction • can be cured easily – in the shade and at ground level • can be batch produced at one site	• Needs skilled craftspeople • Needs good quality control to be effective • Available in one-size-only as frame angles must be recalculated for other sizes

8 COSTS ANALYSIS OF RWH TANKS

The aim of this exercise is to compare tanks from different parts of the world and to carry out a costing exercise so as to assist those considering DRWH to make an informed choice. Such choices are usually complicated by the fact that material costs, labour costs, per capita income, currencies and exchange rates all vary from one country to another. Cost of storage per litre also varies as tank size increases. To take into account this variability an effort has been made to normalise some of the figures.

- 8 tanks have been costed for each of three countries i.e. Uganda, Sri Lanka and Brazil using bills of materials from the designs and material cost information obtained from each of the countries in 2000/2001.
- All tank costs have been converted to $5m^3$ equivalent using sensitivity to size of 0.6.

The tanks under consideration are taken from 4 countries in 3 continents. The countries are Kenya, Uganda (Africa), Sri Lanka (Asia) and Brazil (South America). The tanks are listed in Table 14 and the final costings are in Figure 9

Table 14: Tanks used for costing exercise

	Tank name	Tank size(s)	Source of information
1	PBG Tank	10,800 litres (size can be varied)	DTU Technical Release 01
2	Ferrocement tank	3,000 and 11,000 litres	Eric Nissen-Peterson, ASAL, Kenya (Nissen-Petersen & Lee, 1990)
3	Small brick jar	750 litres	DTU Technical Release 07 (Rees & Whitehead, 2000a)
4	Tarpaulin tank	4,000 – 5,000 litres	ACORD, Uganda and DTU Web Page
5	Ferrocement Pumpkin Tank	5,000 litres	Lanka RWH Forum and CWSSP Reports, Sri Lanka (Hapugoda, 1995)
6	Below ground brick tank	5,000 litres	Lanka RWH Forum and CWSSP Reports, Sri Lanka (Hapugoda, 1995)
7	Cement Plate Cistern	10,000 and 20,000 litres	Johann Gnadlinger, IRCSA. Data from Juazeiro, Bahia State, 1998 (Gnadlinger, 1999)
8	Brick lime cistern	10,000 and 20,000 litres	Johann Gnadlinger, IRCSA. Data from Juazeiro, Bahia State, 1998 (Gnadlinger, 1999)

Figure 9: tank costs in three countries

a Brazil

b Sri Lanka

c Uganda

As can be seen the cost of building the tanks differs by quite some margin:

- The traditional ferrocement tank fares most badly, this is probably due to the design being quite old and suffering many years of "improvements" at various hands
- The Pumpkin tank would appear to provide some savings mainly through its more optimised shape and also due to the youth of the design
- The partially below ground tank also provides good economies with reduced material usage and similar labour costs to other cement tanks
- The brick tanks show some materials savings but a slightly higher labour content tends to favour countries where labour is cheap and materials expensive such as Uganda
- By far the cheapest tank is the tarpaulin tank, due in part to its extensive use of "free" local materials and also because of its quick construction
- The cement plate cistern is also an inexpensive option particularly in countries with cheap cement such as Brazil and Sri Lanka. Its unique construction using closely controlled sections of concrete assembled together on site results in substantial savings in material thickness. In more developed countries, this would be an excellent option as it is both durable and desirable as a household asset

Further insight is gained by discounting the labour content of the tanks as the community itself can often provide this. The Brick lime cistern is a case in point here. In Sri Lanka it is a fairly inexpensive option, however its low labour content means that for a self-help project it is less attractive (in Uganda it is the second most expensive in terms of material use!).

9 CONCLUSIONS

Rainwater harvesting tanks represent a mature technology. Their use goes back many centuries and development has been going on throughout history. This does not mean, however, that there is no room for improvement of the technology. Modern techniques and materials have great potential for the manufacture of rainwater tanks. Some of the most promising areas for cost reduction are:

- Plastic bag tanks such as the tarpaulin tank and the DTU tube tank
- Mass produced parts such as the cement plate cistern and lift on covers

- Partially below ground structures to combine the economies of below ground tanks with the safety and desirability of above ground tanks
- Considering the diseconomies of scale inherent in large tanks and using smaller tanks to provide partial supply or seasonal supply.

In considering cost reduction local conditions play a large part.

- Labour and material costs vary widely throughout both the developing and developed world resulting in different designs becoming cheaper
- Conditions may favour one design over another e.g underground tanks are only suitable for areas with stable soils and low water tables, plastic bag tanks are only suitable where insects are not a problem

These caveats notwithstanding the designs tried within the EU programme and many encountered in the field have demonstrated the cost of tanks can be significantly lowered. Domestic rainwater harvesting remains almost unique in that it allows householders to provide their own water supply without the need to wait for outside intervention and the challenge is to produce a system within the means of every household. With appropriate dissemination, the designs presented in this paper should go some way toward this.

2. Partially below ground tanks 5
3. Thin-shell ferrocement tank covers 9
4. Appendices.....11

*Early in the programme, after the initial desk study had identified the areas where further research is required, it was decided to broaden the original scope of the water storage (technology) component of the programme to include above ground, free-standing water storage tanks as well as underground tanks. The focus of this work, as reported in Milestone A2, has been primarily the research into externally reinforced, single-skin brick tanks. It was also decided that we would put some resources into developing a simple, cheap, lightweight, tank cover, as this was seen as an area where little work has been done and where there was much scope for improvement for relatively little input. The title of this Milestone has therefore been altered to reflect the practical research work that has actually been carried out under the programme.

1. Externally reinforced brick tanks

The early work on this topic was reported in Milestone A2 and covered the early tests that were carried out on brick cylinder specimens that were constructed at the University's civil engineering laboratory.

The aim of the tests were to determine the suitability of single-skin, burnt-brick, externally-reinforced (with packaging strap in this case) cylindrical tanks for water storage. The specimens were subjected to pressure forces in order to determine the hoop stresses induced in the strapping and the behaviour of the brick-strapping combination under load and at failure. The test results were then compared with a spreadsheet model that had been generated earlier.

The early results proved promising but were inconclusive due to some uncertainties in the experimental procedure. Further tests are currently underway at the University to more fully model the behaviour of the tank under load.

Figure 1 below shows one of the specimens under test, showing the internal expansion ring used to apply pressure. Figure 2 shows the steel strapping with a strain gauge that was used to measure the hoop stress generated. For fuller details of the tests, please refer to the Milestone A2 report.

Further work has since been carried out on the construction of a full-sized tank for rainwater storage at a field site in Herefordshire. The tank has a capacity of approximately six cubic metres, with a diameter of 2m and a height of 2m. The tank is at present complete, but without instrumentation as yet. The aim of the experimental tank (shown under construction in Figure 3 below), is to further investigate the behaviour of the tank with particular regard to induced stresses under real conditions and also to investigate the feasibility of a number of peripherals designs.

The tank has been built at the site of a Herefordshire based educational charity who run regular residential courses. The tank will store water captured from the roof of a large shower and toilet complex and the water is then pumped to a header tank from where it is piped to the toilets for flushing. The tank will experience regular cycling (emptying and filling) and hence will allow regular analysis of the stresses and achieve a simulation of accelerated ageing. The cost of the system was shared between the University of Warwick and the charity. The schematic diagrams for the system are shown in appendix 1.

The site will also give us a valuable UK based field testing station at which we can pre-test any idea or component before passing them on to partners or field contractors for further testing and development. The site has already been used to test plastic tank liners which are being developed at the University, as well as being fitted with a novel overflow/ washout system. The system is fitted with WISY filters, which will be tested for efficiency at a later stage.

Figure 1 – Tests arrangement for externally reinforced brick cylinders

Figure 2 – Strain gauge used to measure hoop stress generated in steel strap during testing.

Future work in this area will include research into the use of cement stabilised soil blocks in place of brick, used in conjunction with a plastic tank liner, with the aim of reducing costs further.

Figure 3 – Full-size experimental tank under construction at field site.

Figure 4 – Strapping applied to experimental tank.

Results of the tests carried out at the University and at the field site will be reported in Milestone A5.

2. Partially below ground tanks

The work on partially below ground tanks is still in the very early stages and, to date, has been primarily field based. The work builds on previous DTU work in Uganda with fully below-ground tanks. Modifications were made to the original (fully below-ground) design to eliminate some of the problems commonly encountered with this type of tank, while still taking advantage of the beneficial aspects. These problems are:

- ingress of water from above ground causing contamination
- danger to children (and adults) if cover is left off the tank
- danger of collapse if driven over with a vehicle
- difficulties in excavation due to the construction process (see DTU Working Paper number 'Underground Storage of Rainwater for Domestic Use' at http://www.eng.warwick.ac.uk/DTU/workingpapers/wp49/index.html)
- no suitable overflow when tank overfills

The previous tank design is shown below in Figure 5. Approximately 15 of these tanks, which range from 8 to 10 cubic metres, have been built in western Uganda over the past 3 years with good results.

Figure 5 – DTU fully below-ground tank design

The tank is suitable only under certain soil conditions, namely where the soil is sufficiently stable to not cause any concern regarding subsidence. This is the case in many parts of Eastern Africa where the soil is lateritic.

The partially below ground tank (see Figure 6) is raised slightly above ground level in order to eliminate the problems listed above. The parapet wall sits atop a concrete ring beam through which the tank is excavated. The tank is lined with cement render and will, when the technology is sufficiently developed, be fitted with a continuous plastic lining. Water enters the tank through a pipe which directs it to the base of the tank which promotes rapid settling of sediment. The tank is fitted with an improved handpump and floating off-take. The floating off-take takes water always from slightly below the surface level of the water. These two innovations help maximise residence time in the tank, allowing full sedimentation to take place even when water is drawn off as fresh water is entering (except under conditions where the tank is almost empty).

Figure 6 – Schematic representation of the cylindrical, partially below-ground tank

One partially below ground tank has been built in western Uganda. It was hoped that a number of tests would have been carried out by the time of writing this report, but due

to logistical problems (funds transfer to Uganda which took 3 months), the tank has not yet been tested.

Figures 7, and 8 below, show the partially below ground tank under construction, while Figure 9 shows the thin shell ferrocement cover being manufactured.

Figure 7 – Bird's eye view of the partially below-ground tank under construction.

Figure 8 – Partially below ground tank under construction in western Uganda, showing parapet wall.

Figure 9 – Thin-shell ferrocement cover being manufacture for partially below-ground tank in western Uganda

Further information and test results form this work will be included in Milestone A5 report.

3. Thin-shell ferrocement tank covers

Milestone A2 report included documentation regarding the instructions for manufacturing a thin-shell ferrocement cover (TSF cover).

The thin-shell ferrocement tank cover is designed in such a way that it can be manufactured without the use of a mould or shuttering. It can also be manufactured remote from the tank to which it is to be fitted and moved into place once complete. The aim is to reduce the cost of the tank (cover) by eliminating costly shuttering or moulds and by reducing the quantity of material used to manufacture the cover. It also means that the cover can be removed at a later date for maintenance, refurbishment or cleaning. The cover can be manufactured by two persons (one skilled and one unskilled) in a single day (with some time required after that for curing) using tools required for the construction of a simple cylindrical ferrocement tank.

The design is based on a frame known as a reciprocal frame, that has spokes that, when loaded, put little radial loading onto the structure on which it sits. The frame is covered with a wire mesh that is then rendered with a sand cement mix.

Details of the construction process are given in Milestone A2 for a 2.0m diameter cover that has an inspection chamber opening of 0.5m.

Benefits of the thin-shell ferrocement tank

- low cost – reduced use of materials
- no shuttering or mould required
- strong and lightweight – the tank cover is designed to be strong (through good quality control) and light at the same time
- good quality control can be achieved through easy working environment
- can be manufactured by two people in a single day (one skilled and one unskilled)
- no clambering on top of tanks required during construction
- can be cured easily – in the shade and at ground level
- can be batch produced at one site

Five of these covers have been produced to date, 3 for testing purposes and two that have been fitted to tanks. One has been made in Uganda by local masons (see Figure 9 above and Figures 10 and 11 below) with no complications.

Figure 10 – 6mm steel framework being formed by local masons in western Uganda for the TSF tank cover.

Figure 11 – TSF cover being completed by local mason in western Uganda. This cover was fitted to a partially below-ground tank.

Tests have been carried out on the cover to determine its strength and the results are shown in appendix 2.

1. Introduction

1.1 Project background

This work is being carried out as part of a programme titled 'Domestic Roofwater Harvesting in the Humid Tropics', which is an international 3 year, four partner, European Union funded, programme which started in August 1998.

Warwick is leading the sub-programme titled 'Low cost storage', the aim of which is to develop a number of techniques for construction of low cost water storage tanks or cisterns. As part of the programme we will look at several techniques for reducing costs, improving quality and improving health through good design and construction practice.

One such possible low cost design that will be investigated in detail is the externally reinforced, single skin brick tank. This Interim Report discusses the early research work that has been carried out on this design idea with the aim of clarifying the

findings of this work and the further work that is required to provide enough useful detail to confidently promote such a technology.

1.2 Brick tanks – design philosophy for Developing Countries

The design philosophy adopted for water storage tank design is one of local manufacture using materials that are available with relative ease in the locality. Cost control is of major concern in order that the technology becomes more accessible to the poor of developing countries.

Brick is one such locally manufactured, widely used, readily available material which is ideally suited to wall construction, but not quite so well suited to conventional larger volume tank construction. In this report we look at methods of improving the suitability of brick to low cost tank manufacture by using external steel reinforcing to give additional hoop strength to cylindrical brick tanks. We also look at methods of lining such tanks for water tightness – at this stage limited mainly to internal cement render. Plastic lining of tanks will be discussed in a later report.

2. The theory of stresses in cylindrical tanks

Cylindrical tank walls experience a 'hoop stress' which is proportional to the diameter, D, of the tank, the pressure, p, on the walls of the tank and the thickness of the tank wall, t (Equation 1). The stress on a cylindrical tank wall is also affected by

$$\sigma_t = \frac{pD}{2t} \qquad \textit{Equation_1 – Hoop Stress}$$

the type of joint between the tank base and tank wall. There are two obvious cases to consider as illustrated in Figure 1 below. Taking Case 1, if the tank wall is free to move at its base and still maintain a watertight seal, then the strain induced in the wall will cause the diameter of the tank to increase until the hoop stress is taken up by reinforcing in the wall (obviously the increase in diameter is exaggerated here for effect). In this case the force exerted by the water pressure on the tank walls will be taken up solely by the hoop tension in the walls. The maximum hoop stress will be experienced at the base of the wall and will decrease proportionally (linearly) according to Equation 1.

Figure 1 – The two cases for wall and base union in cylindrical tanks

Taking Case 2, if the wall and base are monolithic i.e. the wall and base are continuous, the situation becomes more complex as bending stresses are set up in the wall as a result of the restraining effect of the base slab. There now exists a complex combination of bending, shear and hoop stresses. Gray and Manning[4] suggest that if the wall is not free to move at its base, then the loading caused by the outward pressure is counteracted by a combination of hoop resistance and cantilever resistance. This is illustrated in Figure 2 which shows the load distribution diagram suggested by Gray and Manning. As the base of the wall is now restrained there is no freedom for the wall to move and take up the hoop stress and so the hoop stress there is reduced to zero. Maximum hoop stress is now experienced higher up the wall of the tank. All the restraining forces acting at the base are due to the cantilever.

Figure 2 – Typical Load distribution diagram for a tank wall which is monolithic with base (modified slightly from Gray and Manning[4].

p_x – Total outward pressure load to be restrained
p_r – Portion of the load restrained by hoop stresses or radial constraints
p_c –Portion of the load restrained by cantilever
x – distance from top of tank
H – total depth of tank

As illustrated in Figure 2, the total pressure p_x at any depth of wall is composed of p_r (the portion of the load carried by the hoop restraints) and p_c (the portion of the load carried by the cantilever), such that,

$$p_x = p_r + p_c$$

The profile of the 'load distribution curve' is governed by the profile of the tank. Gray and Manning give a number of load distribution curves for a variety of tank profiles (see Figure 3). The tank profile is related to the distribution curve by Equation 2, all tanks with equivalent values of K having similar load distribution curves.

Figure 3 – Load distribution curves for a variety of K values (Gray and Manning[4])

$$K = \frac{12H^4}{\left(\frac{D}{2}\right)^2 d^2} \text{.....} Equation_2$$

where,
H = height of tank
D = diameter of tank
d = thickness of wall at foot

It is noted that cantilever load increases for diminishing values of K. K is tightly controlled by the value of H such that K increases to the fourth power of H. We also see that K falls as tank radius and wall thickness increase.

If we consider a typical cylindrical single skin, brick tank with homogenous wall and base of diameter 2m, height 2m and wall thickness of 0.1m, then we obtain a value of K equal to 19,200. This is beyond the value shown in Figure 3 and suggests a regime where p_r dominates i.e. the outward pressure load is resisted predominantly by hoop stresses. Cantilever forces act only at the extreme base of the tank wall (within the bottom 20%). The tank can therefore be dealt with as if the hoop stresses induced are similar to those of a tank with a free base joint. This still leaves the high bending and shear stresses in the base of the wall to be evaluated. Watt[2] suggests that the maximum bending stress on the inside face of the tank wall will be almost double the induced hoop stress for a similar tank profile. This can easily be compensated by increasing wall thickness at the base of the tank. As demonstrated by Equations 3 doubling the wall thickness, d, effectively decreases the bending stress in the wall by a factor of four.

Bending stress, $$\sigma_b = \frac{M\left(\frac{d}{2}\right)}{\left(\frac{bd^3}{12}\right)} = \frac{6M}{b}\left(\frac{1}{d^2}\right) \text{.....} Equation\ 3$$

where, $\frac{bd^3}{12}$ is the Second Moment of area

and b is the width of a strip of wall carrying local bending moment, M

Shear stress is very small compared with the bending and hoop stresses (Watt) and can therefore be neglected for the sake of this analysis.

Work is currently being carried out to develop a computer software programme for a fuller analysis of stresses set up in a variety of tank shapes and sizes.

2.1 Calculating hoop stresses in reinforced brick tanks

The task of calculating hoop stresses in the tank under consideration now becomes a simple task. We treat the tank as if its walls were unconstrained at the base and can thus use Equation 1. We will then deal with bending stresses separately by increasing wall thickness locally at the base as required.

For a tank with a brick wall and external steel reinforcing we need to understand what stresses are induced in each material and what function each material is performing. Table 1 shows a hoop stress analysis for the two materials that have been used during tests at the University. These materials are high tensile steel packaging straps (of 13mm width x 0.5mm thickness), and brick masonry (in this case with cement mortar). If we analyse the two materials separately we can see from Table 1 that the ability of the brick masonry to withstand the imposed hoop stress is unpredictable due to the unpredictable nature of the quality of the material. High tensile steel, on the other hand, has reliable and predictable strength and will afford almost four times the required hoop strength. The steel, then, provides the tensile strength required to prevent failure due to excessive hoop stress.

The brick masonry, on the other hand, provides the stiffness required to prevent failure due to bending stresses. For the example shown below the stiffness of the brick is many orders of magnitude greater that the 'virtual' steel wall stiffness (virtual wall thickness is the thickness that would exist if the straps formed a continuous steel shell - the straps themselves actually provide no vertical stiffness).

We therefore see that one material compliments the other. The steel provides a hoop strength up to eight times that of the brick masonry whilst the brick masonry provides the stiffness that could only be achieved in a steel tank with hundreds of times the quantity of steel used in the example given.

Properties	**High tensile steel strap (13mm x 0.5mm) – two straps per course of bricks**	**Brick masonry**	**Units**
UTS (Mpa)	833	0.1 – 1.0	Mpa
Yield strength	450		Mpa
Youngs modulus	210	25 - 100	Gpa
Wall thickness (equivilant)	173×10^{-6}	0.1	m
Tank diameter	2	2	m
Water depth	2	2	m
Hoop stress exerted by water force	113.19	0.196	MPa
Safety factor	3.98	0.51 – 5.10	

Table 1 – Hoop stress analysis for steel and brick masonry in cylindrical tank of 2m diameter and 2m height

2.2 Construction and application regimes to ensure strength

Some thought has to be given to the interaction between the brick masonry and the steel strap. The two materials must interact in such a way as to enhance the properties of the other as explained in the previous section. This can only be achieved when the construction of the walls and application of the steel strapping is performed in a certain way. The steel is applied externally to the brick wall, using a tool specially designed for applying this kind of strap. The strap should be applied with sufficient pre-tension to be able to counteract the normal water force that will be exerted upon the wall upon filling the tank. In consequence, the masonry is initially put into compression and remains in compression as the tank is filled. This will protect the brick masonry against failure (cracking) should the hoop strength of the masonry be unable to accept the load (due to inferior workmanship or poor material quality). Referring to Table 1, the hoop stress exerted by the water force is 113.19 MPa (say 114 MPa). Experiments were carried out at the University to confirm that such a pre-tension can be applied to the tank and the description and results of these experiments are shown in a subsequent chapter.

2.3 Stresses in tank foundations and base

Little work has yet been done to calculate stresses in the tank base. This will be included in the next report.

2.4 Stresses due to other factors

Stresses due to other factors such as wind forces, cyclic loading and seismic activity have not been considered in this analysis.

3. The theory of cracking in cement render

(This section is the work of Dr. T. H. Thomas from a paper titled 'The Causes and Prevention of Leakage through Cementitious Renders in Water Tanks')

3.1 Cementitious renders

Renders of cement or lime mortar are commonly used in water tanks when the tank itself is constructed of rather permeable materials such as brick, stabilised soil or even (in the case of underground tanks) of unstabilised soil. The render's primary purpose is water-proofing, for which it should have a sufficiently low permeability to protect the main tank material and to reduce water loss through walls to a tolerable level. Thus we might demand that the render keep wall leakage in a 10 m^3 tank to under 1 litre per day. The render may have secondary functions such as reducing the roughness of a masonry surface so that it can be easily cleaned down, or even of providing a little stability to the wall behind it.

Cementitious renders are usually sufficiently impermeable in themselves, but are so brittle and so intolerant of *tensile* strains that they commonly crack. It is the cracks that leak and preventing cracks should be a focus of research effort.

3.2 Sharing out any shrinkage between 'many' cracks

Shrinkage of a render constrained by underlying masonry is the main mechanism for producing cracks. Tensile stresses in the render are relieved by cracking. Tensile

strains are replaced by a combination of strain-free mortar interspaced by cracks carrying no tension forces. For a given shrinkage and a given material, the total volume or total width of cracks may be more or less fixed. However that total may be variously distributed between few or many distinct cracks. Consider for example the inside of a masonry tank of diameter 2 m where a render incapable of supporting any tensile strain has contracted by 1000 microstrain (0.1%) relative to the masonry. Around a circumference we might expect a total crack width of about 6 mm divided between say *n* individual cracks. We would certainly expect the leakage through an individual crack to be a rising function of its individual width. We might expect the total leakage to fall with rise in *n* - e.g. for two 1 mm cracks to leak less than one 2 mm crack.

Consider an individual crack of length L and width W penetrating a render of thickness T across which there is a pressure drop, from liquid to liquid, of p. The leakage velocities are very low and the key dimension (W) is small, so the Reynolds Number will certainly indicate laminar flow. As water behaves as a fairly Newtonian fluid, we can assume a viscous shear stress in the fluid proportional to the transverse velocity gradient in that fluid. Provided velocities are small compared with that corresponding to conversion of pressure head into velocity head, (i.e. $v^2 << 2p/\rho$) this gives a velocity profile of :

$v = \frac{p}{2T\mu}\left(Wy - y^2\right)$ where v is water velocity in the layer distance y from the side of the crack.

The consequent flowrate through the whole (assumed rectangular) crack is:

$Q = L\int_0^W v dy = \frac{pL}{12T\mu}W^3$ which is proportional to W^3, hence Q/W is proportional to W^2.

This suggests that replacing one large crack by two smaller (half-width) cracks will usefully reduce leakage by a factor of 4.

Inserting numbers: a 100 mm long crack of width 0.1 mm in a render 10 mm thick and subject to a water pressure of 10 kPa (1 m head) will leak 20°C water (μ = 1 mPa s) at nearly 750 litres per day. Replacing this crack by ten 0.01 mm cracks will reduce leakage to 7.5 litres per day. Even this is usually unacceptable, so we are looking to get crack widths below 10 μm. However at these capillary sizes, surface tension effects become dominant.

Surface tension is likely to prevent *any* flow through a plane crack whose thickness W is less than $2\gamma/p$ where γ is the surface tension of water (in Nm^{-1}). Thus for water at 20°C for which γ = 72.5 mN/m, a head of 1 m will not cause leakage through a gap smaller than 14.5 μm.

3.3 Prevention of cracking or of leakage through cracks.

Render cracks may form during ‘manufacture’ of a tank or when water pressure is first applied after manufacture or during moisture cycling through the life of a tank. We are studying the various shrinkage and crack-formation mechanisms associated

with cementitious materials. Generally such materials experience shrinkage of up to 2000 μstrain.

Strategies to prevent or reduce leakage through cracks include:

	Approach	Technique
a	Use non-shrinking render	1. Use mortar with very low water content 2. Pre-shrink the render 3. Cure under water
b	Remove the constraint provided by underlying masonry/reinforcement	1. Add reinforcement after curing 2. Use flexible mortar to lay bricks/blocks 3. Use very-slow setting mortar to lay them 4. Masonry same as render
c	Reduce constraint of base plate	1. Flexible or sliding wall-base joint 2. Thicken wall to reduce bending stresses
d	Distribute cracks (convert into more but smaller cracks)	1. Reinforce with mesh 2. Reinforce with fibre 3. Manipulate bond with masonry
e	Stagger cracks in multi-layer render	1. Plaster, cure, replaster 2. Plaster, cure, groove, fill
f	Use a flexible render	1. More (hydraulic) lime in mix 2. Add polymers like latex to mix
g	Prevent cracks opening under stress (strain induced by water pressure)	1. Hoop tension the reinforcement after curing the render 2. Do so before curing the render. 3. Thicken the masonry to reduce changes in strain when under load.

Table 2 – strategies for preventing cracking in cementitious renders

4. Building materials

One of the aims of this research is to investigate the behaviour and suitability of the materials listed in this chapter for use in construction of a water storage tank and to make recommendations for tank construction techniques using these materials. Tests and test results are shown later in this document. Now we will discuss the general nature of the materials and the general theory postulated for design.

Fired clay brick is a rigid, brittle building material. It is usually used in conjunction with a cementitious binder (such as cement or lime mortar) to form a wall which is strong in compression but weak in tension. There are a number of techniques used to give extra strength where required: this usually takes the form of laying the bricks in a

regular pattern to form an interlocking matrix of brick and mortar. Ties, buttresses, and other building aids and techniques give extra, localised strength where required. It is difficult to improve the tensile strength of brick masonry without creating a composite material by adding steel or timber.

The predominant stresses that will be set up in a tank wall are tensile stresses. As explained in an earlier section, these stresses are due to the water in the tank exerting hoop stresses and bending stresses in the structure. The brick and mortar construction alone cannot be expected to withstand these stresses and it is for this reason that steel strapping is used to take up the predominant tensile stresses. The brick gives rigidity (i.e. stiffness) and mass to the structure while the steel, with it's high tensile strength, performs the task of providing hoop strength. Together, using the cylindrical wall structure, they combine properties to provide a rigid structure with sufficiently high tensile strength.

A further requirement of the tank wall material is that it be watertight, and that it remain watertight for the lifetime of the tank. Brick masonry rarely achieves this requirement and so we will also look at methods of providing a waterproof membrane or lining within the tank. Therefore, we also look at cementitious renders which are applied to the inner surface of the tank wall to provide a continuous waterproof membrane. Later (in a later report) we look at low-cost plastic liners for water tanks.

We investigate the properties of these materials used together (brick masonry – steel – mortar render) to determine the optimum design specification that will give adequate strength, rigidity and watertightness, while minimising the quantity of material used (with the aim of keeping costs to a minimum). Each of the individual materials mentioned above has it's own unique behaviour and the biggest challenge comes in trying to match these materials in such a way that they act in synergistic fashion to provide a composite that gives the required properties.

Much thought has been given to the process required to achieve this synergy. A number of mortar and render types have been investigated and the methods of application and construction regimes have been considered carefully. In this report we will look in some detail at the following aspects of tank design and construction:

- behaviour of lime and cement mortars
- application of steel strapping to cylindrical steel tanks
- stresses in steel strapping in cylindrical brick tanks during application and under load conditions
- initial investigations into shrinkage and cracking in thin renders

4.1 Tank construction materials

Fired clay brick.

Low quality fired clay brick is a building material which is commonly found in many, many countries throughout the world. Brick masonry is a building technique that has existed for more than 4000 years. A variety of soils are available for the process of brick making and the process itself varies in complexity from small field based batch kilns capable of producing a few thousand bricks to large scale continuous mechanised technology capable of producing hundreds of thousands of bricks per day.

Cement mortar.
Nowadays, the most common methods of bonding fired clay bricks is with cement mortar. Cement mortar is a hydraulic binder made from a controlled mixture of sand and Ordinary Portland Cement (OPC), with or without a variety of admixtures that improve the properties of the mortar. Plasticisers are used to reduce the water requirement of mortar and hence improve strength, or to improve the workability for a given water content. Bagged lime is sometimes added to improve workability. A typical mortar would be made up of 1 part OPC to 4 parts clean, well-graded sand, although the quantity can vary enormously depending on strength requirements.

Lime mortar.
Lime has been used as a building material for over 2000 years. To make a lime binder or mortar, calcium carbonate (limestone) is burnt at a temperature of about 900°C to drive off the carbon dioxide and produce calcium oxide (quicklime). The quicklime is then 'slaked' (water is added) to produce hydrated lime powder. If further water is added a lime milk is formed and this is allowed to settle and mature for some time (months) in a pit to form a lime putty. This can then be used for a variety of applications including mixing with sand to form a lime mortar.

Lime mortars have certain benefits over cement mortars. The lime mortar slowly absorbs carbon dioxide from the atmosphere and this causes the mortar to harden as it returns to it's initial state as limestone. This process can take many years and in the meantime the mortar remains plastic. This can be beneficial where flexibility is required or where other less flexible materials are used in close proximity.

5. Reinforcing materials

5.1 Choice of reinforcing material

A number of materials were considered for use as external reinforcing for the tank. There are examples of similar designs from Thailand of brick masonry and steel wire tanks (Vadhanavikkit[6]), and from Uganda of stabilised soil cement blocks with barbed wire reinforcing (personal correspondence with Mr. Kimanzi Gilbert of the Uganda Rainwater Association) and other examples of brick and barbed wire tanks from Botswana.

As mentioned in the introductory chapter it is important that the materials used for the tank construction be available widely in the areas where they will be built (less developed tropical regions) and that the materials be of low cost. Those materials mentioned above i.e. steel wire and barbed wire, as well a number of other similar materials are readily found for other construction and agricultural applications.

In the cases mentioned above there is some concern (on our part) as to the control of the application of the reinforcing material and the amount of tension that can be achieved and maintained. Tying knots in wire, and maintaining tension at the same time, is a difficult business, especially when the wire needs to be tight against the

surface of a wall. We are therefore considering packaging strap as an alternative for the following reasons:

- it is widely available in any country where there is a reasonable manufacturing base;
- the strap is ideally suited to this application with a high tensile strength and flat surface that lays flat against the brick face;
- it is cheap once the tools have been purchased (even the tools themselves are not prohibitively expensive for a mason of reasonable standing). More research is currently underway into prices of strap and tools in developing countries;
- application is easy with the dispenser, tensioning and crimping tool
- a high pre-tension can be easily applied to the strap applying compression forces to the masonry.

Depending on feedback from a number of countries (Sri Lanka, Uganda, India, Kenya in particular), we will later reassess the suitability of this material and possibly look at alternatives.

5.2 Spacing of steel straps

Following on from Chapter 2.1 we are now able to calculate the spacing for the steel strapping, assuming pure hoop stresses are induced by the outward water pressure.

Virtual wall thickness, $t = \frac{w \times t_s}{s}$ ..... *Equation 5*

where, w = strap width
t_s = strap thickness
s = maximum strap spacing

Maximum strap spacing, $s = \frac{2\sigma_{ma} w t_s}{\rho g H d}$ ..... *Equation 6*

For the tank considered in Table 1, we can rearrange Equations 1 and 5 to give Equation 6. If we specify a value for maximum acceptable hoop stress in the strap, $\sigma_{ma,}$ of say 150 Mpa (one third of the yield strength of the steel), we can easily calculate the strap spacing using a simple spreadsheet calculation. Table 3 below is the data output from such a spreadsheet calculation for a small variety of tanks of a similar size and profile to that being considered.

	Distance from top water level						
Tank diameter (m)	<0.5m	0.5m - 0.75m	0.75m - 1.0m	1.0m - 1.25m	1.25m - 1.5m	1.5m - 1.75m	1.75m - 2.0m
1.00	398	265	199	159			
1.25	318	212	159	127			
1.50	265	177	133	106	88		
1.75	227	151	114	91	76	65	
2.00	**199**	**133**	**99**	**80**	**66**	**57**	**50**
2.25			88	71	59	50	44
2.50				64	53	45	40

Table 3 – Maximum strap spacing for a variety of tank diameters and depths

It can be seen that the minimum strap spacing (at the base of the wall) is less than the thickness of one course of bricks (80mm) and so two straps will be used on each course of bricks, giving a spacing of approximately 40mm.

6. Laboratory experiments

6.1 Introduction

The experiments described in this chapter were carried out at the University of Warwick between January and April 1999. Forming the basis for the tests were a number of brick masonry cylinder specimens built on a civil engineering 'strong floor'. Such a specimen is shown in Figure 4 below. The specimens were of internal diameter 1.5m and varying height. These specimens allowed experimentation and observation of mortar behaviour, cracking of renders with a number of different additives, application and loading of steel packaging strap, as well as providing through practice an insight into the merits of the construction technique.

Figure 4 – Brick masonry cylinder specimen

6.2 Mortar observation – lime and cement mortars

Two types of mortar were used for constructing the cement mortar specimens; cement mortar and lime mortar. The main purpose of this test was to observe the following:

- the plasticity of the mortar and the associated ability of the brick masonry to 'move' in compression;
- the behaviour of the brick masonry under load – particularly the load transfer characteristics of the masonry;
- render behaviour (particularly cracking) when applied to each type of brick masonry.

The cement mortar is composed of the following:

Sand cement ratio	5:1
Water cement ratio	0.5 (i.e. water content 50% by weight of cement)
Mortar plasticiser	10% of water content

The lime mortar is made up of 3 parts well-graded sand to one part lime putty. No water is required.

The first part of the experiment consisted of simply observing the brick masonry when applying the steel strap for signs of movement and, secondly, observing the tension in the strap to determine the ability of the masonry to go into compression without distortion (i.e. that the masonry is sufficiently rigid). Early in the experiment it was decided that the lime masonry was insufficiently rigid in the early days after construction and that, without further investigation of its properties it would be unwise to use this material for this application. Although the characteristic property of lime mortar to remain plastic can, in some cases, be a positive advantage (we subsequently see that render cracking is greatly reduced - almost eliminated even - when using lime mortar), it does mean that a wall built using lime mortar will be far less rigid than its cement mortar equivalent.

Cement mortar gives a strong, rigid wall with no sign of movement during application of the strapping. The load that can be applied to a cement mortar, brick masonry tank is outlined in Graphs 1 and 2. The figures shown in this graph demonstrate the rigidity of the material at characteristic loads (and beyond). Detailed tests of this nature have not been carried out to date on the lime mortar specimen, but visually the wall of the lime mortar specimen can be seen to move when strapping is applied.

The behaviour of renders on each of the specimens is detailed in the following chapter.

6.3 Render – shrinkage and cracking

A number of tests were carried out to observe cracking of renders of different types on specimens constructed with two different mortar types (cement and lime mortar). The base render was made up of 4 parts sand to one part OPC and a water content of 0.4 (this was slightly exceeded in most cases to provide a workable render) Mortar plasticiser was added in all cases at 10% of water content. The render thickness varied due to the uneven surface onto which it was being applied, but in general the thickness remained within 5 – 15mm. After a day the wall was painted with a thin white paint to help with the location of cracks (see Figure 5 below). Any visible crack was measured using a hand held x20 microscope. Shrinkage was measured by observing the separation of the render from the wall at the top of the specimen. In

Table 5, separation is indicated as a percentage of the visible joint line over which separation occurred and the minimum and maximum value of separation width (in mm).

Figure 5 – Cracks in renders

The additives used during the tests are shown below:

- **Mortar plasticiser** – a proprietary plasticiser used for mortars and renders in the building industry.
- **Re-in fibre** – a polypropylene fibre of 50 micron square cross-section and 6mm in length. This is a UK construction industry building material used for preventing cracking in thin renders and screeds.
- **Febond SBR** – a proprietary waterproofing solution for use in renders and for other application. It is a styrene-butadiene co-polymer latex specifically designed to improve water resistance and durability.

Five render types were tested. All were cement based renders. These are listed below in Table 4.

Render type number	Sand : cement ratio (by weight)	Water cement ratio (by weight)	Mortar plasticiser content (as %age of water)	Other additive	Curing regime
01	4:1	0.4 – 0.5	10%	none	basic*
02	4:1	0.4 – 0.5	10%	none	7 days**
03	4:1	0.4 – 0.5	10%	re-in fibre	basic*
04	4:1	0.4 – 0.5	10%	re-in fibre	7 days**
05	4:1	0.4 – 0.5	10%	sbr	7 days**

Table 4 – composition of renders used for cracking and shrinkage tests
*** basic infers no special curing regime employed – render left to cure in open air**
**** 7 days curing under soaked Hessian cloth**

Cement mortar used to lay bricks					
Render type (see Table XX)	Ave. crack length (mm)	Crack length per (mm /m^2)	Ave. crack width (mm)	Maximum crack width (mm)	Separation *

01	No test				
02	0	0	0	0	no separation
03	No test				
04	0	0	0	0	no separation
05**	69.33	2207	0.32	1.3	no separation

Table 5 – Cracking in cement renders – values for a number of test results after 7 days
*** Separation given as a percentage of separation at the visible joint around the perimeter at the top of the specimen wall. Variation in crack width also given.**
**** although manufacturers instructions were followed carefully there is some concern about the validity of these results – possibly an incorrect quantity of SBR was added to the render.**

The results given in Table 5 lead us to a number of tentative conclusions:

- the re-in fibre (renders 03 and 04) significantly reduces cracking in renders;
- improved curing of renders on cement mortar wall (renders 02, 04 and 05) helps prevent separation at the cost of increasing cracking i.e. adhesion to the wall improves causing greater cracking – this is advantageous if we then seal the cracks with a nil coat (cement slurry) or other proprietary sealant ;
- separation of render is much greater on cement mortar walls due to the rigidity of the wall. In the case of lime mortar, the wall moves as the render shrinks, preventing cracking – as mentioned in an earlier chapter this is very beneficial for achieving crack-free renders but not so beneficial in terms of loss of rigidity.
- no conclusions are made about the characteristics of SBR render due to uncertain results

Further work is required to gain a better understanding of renders and their behaviour on internal tank walls. This work is outlined in the final chapter of this report.

6.4 Reinforcing straps – initial tensile strength tests

Initial tensile strength tests were carried out on a number of packaging straps to determine the strength of each (manufacturers specification was not available for all). The aim of the tests were to investigate the strength of woven polypropylene strap and the effect of crimping steel straps. The tests were carried out at the Universities civil engineering laboratory using the tensometer machine (see Figure 6).

Without going into detail here it can be stated that the *polypropylene* strap was insufficiently strong for the application under consideration with an Ultimate Tensile Strength half that of steel with ten times the strain.

In all cases the singly crimped steel band broke at the crimp at well below maximum UTS. During practical tests on the brick specimens, in which the strap had been fitted with two crimps, the strap broke remote from the crimp at a value close to UTS.

6.5 Reinforcing straps – applying the strap

This experiment aimed to investigate:

a) the pre-tension set up in the reinforcing straps during application with the tensioning tool - as mentioned in chapter 2 it is necessary that sufficient pre-tension exists in the strap after application to support the masonry in compression and prevent cracking when the tank is initially (and subsequently) loaded.
b) the distribution of the tension in the strap upon application – this experiment was to test the assumption that circumferential tension in the strap would vary due to the friction between the wall and the strap, from a maximum near the tensioner, to a minimum on the opposite side of the tank.

The experiment involved measurement of the strain in the reinforcing strap using strain gauges. The strain gauges had been calibrated beforehand (see Figure 6 below) so that the load in the strap could be derived directly and accurately from the strain values. Three strain gauges were placed on a single strap, at 0, 90 and 180 degrees around the specimen circumference, and readings taken as the strap was applied (see Figure 7).

Figure 6 – Calibration of strain gauges using tensometer

Figure 7 – Showing strain gauge fitted to the steel strap

Box 1

Applying the steel strap
The strap is applied to the brick masonry specimen using a manually operated tensioning tool. Once fully tensioned the strap is crimped (see Figure 9 below) using specially designed crimps and crimping tool and then the tensioning tool is removed. It can be seen from Figure 8 below that the tensioning tool holds the strap away from the wall in order to allow access for the jaws of the crimping tool. After initial experiments there was some concern about the loss of tension when the tool is removed.

Graph 1 shows the steps taken during the experiment and the load registered by the strain gauges. The term 'redis' in the graph means redistribution of the load. This was achieved by using a screwdriver to prise the strap away from the masonry slightly (moving around one brick at a time) to allow the tension in the strap to be redistributed.

Box 2

Strap pretension required to balance water pressure forces and prevent tensile stress being set up in masonry
- From Table 1, maximum hoop stress in steel due to water pressure is 114 Mpa
- Area of cross section of steel strap = 6.5mm^2
- Tension required in strap = 6.5 x 114 = 741 N

An analysis of the graph clearly shows the increase of tension in the strap as the strap is tightened and also shows that a certain amount of redistribution of that load takes place during the 'redis' phase. The drop off in tension during removal of the tool without packing (as illustrated in Figure 8) is completely unacceptable with the final tension being a small fraction of the tension created by the tool and insufficient to put the masonry into compression (see Box2). We see, however, that the tool is capable of tensioning the strap sufficiently – values of almost 2000 N being achieved during the tensioning phase.

Graph 1 – Distribution of load in steel strap around cylindrical brick tank during application

Figure 8 – showing tensioning and crimping arrangement for steel strapping a/ during the tensioning and crimping process b/ when crimping is complete and the tensioning tool has been removed and tension reduced c/ maintaining tension by using packing

Figure 9 – photograph of straps showing crimps

Figure 8 shows the method used to pack the strap to prevent loss of tension upon removing the tensioning tool. If this process is carried out the tension can be maintained as shown in Graph 2. In this case the tension, at 1777 Newtons, is more than double that required to prevent the masonry going into tension upon pressure loading. Practically, this involves placing some packing material behind each strap as it is applied. Further work is needed to define a practical method and a suitable material for this purpose.

Graph 2 - Distribution of load in steel strap around cylindrical brick tank - application mode with packing (shown for strain gauge at 0 degrees only)

6.6 Reinforcing straps – loading and ultimate tensile strength

A test was carried out to determine the maximum load that can be applied to an externally reinforced brick tank. The aim of the test was to simulate water pressure acting on the wall of the tank and to observe the behaviour and failure mode of the tank as pressure was increased. Ideally the test would have been carried out using a sealed tank that could be pressurised to the point of failure but this was not practical at the University, especially indoors on the civil engineering strong floor. To simulate water pressure a steel expansion ring was manufactured as shown in Figure 10 below. The ring was made from 3mm mild steel to provide enough rigidity to prevent buckling but enough flexibility to take up the shape of the interior surface with which it came into contact. The ring was expanded using two 1 tonne hydraulic jacks, as shown in Figure 11. A load cell was placed in series with the jack to measure the applied load and is also shown in Figure 11 (this had been calibrated earlier). The ring spanned 2 courses of bricks that with hindsight, should have been free floating, but were not. The straps on the specimen were fitted with strain gauges at 0°, 90°, and 180° to measure the stress induced in the strap. Thus we could monitor the increase in load in the strap due to increased (simulated) water pressure.

Figure 10 – Specimen under test, showing expansion ring

As the hydraulic jacks were extended the ring slowly expanded putting the strap into tension. The jacks continued to be extended until the straps failed and the masonry broke. During this time observations were made of the following:

- the applied load
- the cracking of the render
- the cracking of the masonry
- the strain (and hence load) in the strap

Graph 3 (histogram) shows the general trend of increased load in the straps as the expansion ring is opened. Noting the horizontal axis of the histogram we see that jack pressure in the expansion ring is not rising continuously. Graph 4 shows a clearer representation of what is happening in one of the straps – namely the strap at 90°. There are some interesting phenomenon to observe:

1. Firstly, the force in the expansion ring is much greater that the force in the strap. There are a number of possible explanations for this:
    - the two courses of brick under test are not free-floating and so some energy is being required to stress the lower courses of bricks
    - in the early stages of the test, until the masonry fails, some of the load is taken by the masonry itself
    - there are four straps fitted on the specimen, all of which are accepting some of the load – two strap are directly under load

2. We see two distinct regions (see Graph 4 below), one where the pressure in the ring rises linearly with the load in the strap (region 1) and then a region where the pressure in the ring rises little, and indeed starts to fall, as the load in the strap increase and the ring continues to expand (region 2). This can be explained as follows (either or both of the following acting at any time):
    - as the cracking in the specimen worsens, the energy that was taken up 'bending' the lower part of the wall is now redistributed in the upper part of the wall (the test area) as the joint between the two fails.
    - the masonry breaks locally, and there is a significant repositioning of the brick (local to the ring) within the masonry as the ring expands further.

Graph 3 – Loading cylindrical tank using expansion ring

3. Large vertical and horizontal cracks appear (see Figure 12):
    - the horizontal cracks are due to shear as the upper section of the specimen wall shears away from the lower section
    - the vertical cracks are obviously the result of tension as the pressure is applied to the ring

Figure 11 – Specimen under test, showing close up of hydraulic jack and load cell

Figure 12 – Cracking in specimen after pressure test

Graph 4 – Pressurising cylindrical tank using expansion ring – strain gauge readings at 90 degrees

In conclusion it should be strongly noted that although what we see is a realistic representation of what was going on in the test specimen during the test, and is of some value to us in understanding the behaviour of cylindrical tanks, it is not what we were looking for! This was due to improper experimental design. A further test will be carried out on a free-floating specimen i.e. a specimen set on a sliding ring to simulate an elemental horizontal slice of tank. This will hopefully yield results that will be of more interest to us.

7. Conclusions

The general conclusion is that the single skin, externally reinforced, brick tank is a viable alternative to more costly tank types available at present. The experiments carried out so far have shown that the construction technique adopted is sound, but further work is still required to achieve a full analysis of the ideas under discussion which will lead to a final design and set of construction guidelines for this type of tank. The work that still needs to be carried out is outlined in the following Chapter

8. Further work to be undertaken

The following have been identifies as areas needing further work:

From section number:	Description of work
1.2	Research into plastic linings for tanks
2.1	Carry out full computer analysis of stresses in cylindrical tanks
2.3	Analysis of stresses in foundations of tanks Foundation design
2.4	Analysis of stresses due to other forces (e.g. wind, earthquakes)
5.1	Research the alternatives to steel strap e.g. methods of adequately tensioning steel or barbed wire
6.2	Further tests on lime mortar specimens - strap application and loading tests
6.3	Further tests to characterise the behaviour of renders – cracking, shrinkage and adhesion with a variety of admixtures and curing regimes
6.6	Tests of free-floating brick cylinder specimens using both cement and lime mortars
Other	Preparation of design and construction guidelines for this style of tank. Construction of full size tank to look at the following: ▪ tank construction techniques ▪ stress analysis in full size tank – including cyclic loading and temperature effects ▪ shrinkage and cracking due to water pressure loading ▪ leakage

February 1999

Introduction
The thin-shell ferrocement tank cover is designed in such a way that it can be manufactured without the use of a mould or shuttering. It can also be manufactured remote from the tank to which it is to be fitted and moved into place once complete. The aim is to reduce the cost of the tank (cover) by eliminating costly shuttering or moulds and by reducing the quantity of material used to manufacture the cover. It also means that the cover can be removed at a later date for maintenance, refurbishment or cleaning. The cover can be manufactured by two persons (one skilled and one unskilled) in a single day (with some time required after that for curing) using tools required for the construction of a simple cylindrical ferrocement tank.

The design is based on a frame known as a reciprocal frame, that has spokes that, when loaded, put little radial loading onto the structure on which it sits. The frame is covered with a wire mesh that is then rendered with a sand cement mix.

Details of the construction process are given here for a 2.0m diameter cover that has an inspection chamber opening of 0.5m. The cover pitch is 25°. Strength tests have proved acceptable up to this diameter. No guarantee is given for greater diameters. The spoke angles have to be recalculated for different diameters – this is one disadvantage of the cover design.

Benefits of the thin-shell ferrocement tank
- low cost – reduced use of materials
- no shuttering or mould required
- strong and lightweight – the tank cover is designed to be strong (through good quality control) and light at the same time
- good quality control can be achieved through easy working environment
- can be manufactured by two people in a single day (one skilled and one unskilled)
- no clambering on top of tanks required during construction
- can be cured easily – in the shade and at ground level
- can be batch produced at one site

Reciprocal frame construction guidelines – for 2m diameter cover

Materials and tools

Materials	Tools
♦ 8mm reinforcing bar – 40m ♦ tie wire – 0.5kg ♦ chicken mesh (0.9m wide; 10m long; ½" mesh) ♦ sand ♦ cement ♦ mortar plasticiser ♦ water ♦ plastic sheeting (reusable)	♦ hacksaw ♦ pliers ♦ tin snips ♦ vice (handy if available) ♦ masons trowel (small) ♦ masons trowel (large) ♦ plasterers float ♦ shovel ♦ buckets (2) ♦ wheel barrow (optional)

Stage 1 – making the frame

- Choose a location with plenty of space to work. The procedure requires bending long lengths of reinforcing steel and so a clear working area is essential. Also a ground space of 2m diameter will be needed where no other activity will be carried out for a week (while the cover is cured).
- The first step is to set up a jig for bending the reinforcing bar. The jig is made up of two pegs 5cms long, set about 5cm apart. The steel is placed in the jig and bent as shown in Figure 1. The jig needs to be fixed so that it cannot move when the steel is bent. A workbench is ideal where the pegs can be put into the vice. Alternatively the pegs can be driven into a heavy piece of timber and this arrangement can be used effectively. Steel re-bar (8mm) can be used to form the pegs, but slightly heavier steel is better.

Figure 1 – Jig for bending steel reinforcing bar

Tip:
When bending the re-bar it does not bend exactly where it makes contact with the jig peg. The bending takes place a cm or two on the pulling side. This has to be allowed for when bending. The bending radius can be quite large because of the thickness of the steel. This doesn't present any real problems here.

- The next step is to bend the 8mm reinforcing steel into hoops. Four hoops, diameter 0.55m, 1.0m, 1.5m and 2.0m are required. To make the procedure easy, a peg can be knocked into the ground and used as a centre around which the four circles can be drawn using string and a marker (also mark the positions of the 8 spokes at 45° intervals for later use). The steel can then be bent gently in the jig to match the circles. The hoops ends are tied with two or three pieces of tie wire. For this the steel is cut slightly oversize to allow for tying. The cutting lengths are given in Table 1. Where the cover is to be fitted to an existing tank the outer hoop should be bent to fit the mean radius of the top of the tank wall and any irregularities in the shape should be taken into consideration.

Diameter	Steel cutting length (add 0.2m for overlap for tying in all cases)
0.55m	1.72m (1.92m)
1.0m	3.14m (3.34m)

1.5m	4.71m (4.91m)
2.0m	6.28m (2.48m)

- At this point all but the outer (largest) hoop can be put aside until later.
- The next step is to bend the spokes. There are eight in number and are bent in the jig to the dimensions shown in Figure 2. The cutting length is 1.33m. To aid the bending, the angles can be marked out on the ground (or on a bench) beforehand and then the bent steel can be matched against this. The angles to mark are:

Figure 2. Dimensions and locations of frame spokes

- It is recommended that Angles 1 and 3 are bent first. These are bent in the same plane. The spoke is then turned through 90° and Angle 2 is bent.
- Eight secondary spokes are also cut to a length of 75cm. These are wired to the frame as shown in Figure 3 and support the mesh to reduce the 'panel' size.

Figure 3. Secondary spokes in place

- Now the spokes are placed one by one inside the outer hoop (as shown in fig 2.) to slowly form the cover frame. It is convenient to have the outer hoop sitting on the ring marked out earlier with the position for the 8 spokes marked also. THERE IS NO INNER RING. This is made up as the separate spokes are joined together. (See Figure 4). Spoke one is placed on a support (a box or piece of wood) which is 35cm high. This is the height of the frame from the ground to the plane of the circular cover opening.

Figure 4. Showing the formation of the inner ring from individual spokes

- Tie the first spoke to the inner side of the outer hoop as shown in Figure 5.**(no 11).**

Figure 5. Showing arrangement for tying spoke to outer hoop.

- Place the next spoke 45° around the perimeter hoop (these spacings were marked earlier) and tie it to the first spoke as shown in Figure 6. Continue in this way until the final spoke is tied to the first spoke and all eight spokes are in place.

Figure 6. Arrangment for tying spokes to each other.

- Put the two inner hoops in position and tie them in place (Figure 7). The small inner hoop that was formed earlier will be used when the access hatch lip is made later.
- The frame in now ready to have the chicken mesh attached.

Figure 7. The frame with hoops in place.

- Use chicken wire of 0.9m roll width with a mesh size of ½ inch. Ten metres length is required. Two layers of chicken netting are applied.
- Eight pieces of chicken wire are cut to the dimensions shown in Figure 8. Two pieces can be cut from a 2.4m length of netting if cut as shown. A template can be drawn on the ground to aid cutting.

Figure 8. Cutting size for chicken mesh

- The pieces of netting are placed on the frame as shown in Figure 9 and Figure 10 and the overlapping edges are folded over and tied in place, pulling the wire as tight as is possible without distorting the mesh. Use the rough edges of the netting to tie the folded edges into place. Use as little tie wire as possible at this point, as the netting will tied securely when the second layer is in place.

Tip: a screwdriver can be used to pull the loose wires or end loops through holes in the mesh to tie the mesh in place.

Figure 9. Pattern for application of chicken mesh

Figure 10. Applying the chicken mesh.

- When the first layer is complete start the second layer one spoke out of phase with the first and complete in the same manner.
- Carefully check that the mesh is folded as flat as possible and that both layers are close together. Tie the netting at regular intervals using the tie wire so that the netting is close to the rebar. Bend all tie wires into the plane of the cover. Remember that we are trying to keep the cover as thin as possible.
- The cover is now ready for the rendering (Figure 11).

Figure 11. Cover ready for rendering

Stage 2 - Rendering the cover

Materials

Sharp sand – 150kg
OPC – 30kg
Mortar plasticiser – 0.5 litres (soap powder can be used as a substitute)
Water - 20 litres (approximately)

Procedure

- It is important to use good quality materials and to maintain good standards of workmanship throughout the rendering process. The aim is to apply a layer of mortar to the chicken mesh that is as thin as possible. This, in practice, will vary between about 15mm and 25mm with an average thickness of about 20mm. The first coat is applied from the top and second coat applied from below.
- Put a plastic sheet on the ground so that render mix which falls through during rendering can be reused.
- Elevate the frame so that work can be carried out from above or below. Waist height is most suitable. The frame should be raised on 4 posts or boxes so that it is stable and can withstand the forces applied during rendering. A support should also be placed in the centre to prevent the centre sagging under the weight of the render (see figure 11 above).
- Render preparation: a mix of 3:1 (sand:cement by *volume*) is used. A sharp sand should be used i.e. not a fine sand but sand with a moderately large grain size. There should be no silt or other contaminant in the sand. (**See guidelines for checking sand quality)**. Ordinary Portland Cement (OPC) is used. The quantities should be carefully measured using a container – a bucket for example (do not measure using a shovel as this can be very inaccurate).
- The consistency of the render is very important. It should be dry enough not to fall through the netting while being plastic enough to be workable with a trowel. A mortar plasticiser is required to improve the workability of the render. This means that the water:cement ratio can be kept low while still keeping the render plastic. This ratio should be kept to approximately 0.4 by weight (i.e. 10 parts cement to 4 parts water by *weight*). Low water content not only gives a render which is easily applied to the mesh, but also gives improvements in strength and permeability of

the cured render. In practice it is difficult to control the water:cement ratio because there is usually an unknown quantity of water in damp sand and plasticity is often achieved before the minimum measured ratio is met. The practical method involves experimentation to achieve the desired plasticity with minimum water content. The plasticiser should be used according to the manufacturers instructions.

Tip: use soap powder instead of mortar plasticiser. Experiment to find a suitable quantity.

- Keep mixes small because the render 'goes off' quickly. It may be wise to mix enough render for the whole job and then add water to small amounts as required.
- Applying the render: this is fairly simple to do. Use a plasterers float and a small trowel. Put the float behind the mesh and work the mortar through the mesh onto the float as shown in Figure 12. Wipe the float away so that the mortar is slightly smoothed on the underside. Work small areas – take one 'panel' at a time and complete it. Some of the mortar will fall through onto the plastic sheet – this can be picked up immediately for reuse. Remember that the aim is to apply a very thin layer of mortar. The technique can be easily learned with a little practice.

Figure 12. Applying render to the chicken mesh.

- Where the cover stands on the supports, leave a small section of the outer hoop un-rendered. Wires can be threaded through these gaps later for lifting the cover into place and any securing to the tank body can be done here.
- The outer edge of the tank should be rendered roughly as this will blended into the tank wall when it is put into place.
- Once the first layer of mortar has been applied the cover should be left for a day to allow the render to gain strength.
- The area within 10cms of the inspection opening should be roughened for keying in the lip. A strip 20cms wide from the outer edge to the inner edge should also be roughened to take the access strip (see Figure 13). Tie wires should also be poked through from the underside to tie the access strip reinforcing in place when the render has gained strength.

Figure 13. Showing finished access strip and old tyre used as former for access hatch lip.

When the rendered cover has been sitting for one day the following work can be done:

- Three lengths of steel should be cut and placed radially where the access strip is to be located. They are tied in place. The access strip is then laid using 3:1 mix render to a depth of 2cms. This is then scored to give grip when climbing to the access hatch.
- The lip of the inspection chamber is built up with mortar to a total thickness of 4cms. The 0.55m steel hoop of is placed on top of the existing render and the lip built up to the desired shape. A former can be manufactured to aid in this process or an old car tyre can be cut to give the correct diameter and supported in place (see figure 133 above). A greater lip thickness gives a greater feeling of security to people working on or in the tank.
- The cover is then cured for 7 days. The tank should be wetted twice daily and covered with plastic sheeting to prevent evaporation of the curing water. It is essential that curing is carried out properly.
- A coat of ‘nil’ (pure cement water slurry) is applied to top and bottom after two days of curing.

Putting the cover in place on the tank

- When the cylindrical tank body is being constructed some thought should be given to the method of fixing the cover to the tank. If the cover is to be fitted to a thin walled ferrocement tank four (or more) tie wires should be left protruding from the tank wall and these are tied to the cover when it is in place. For brick, block or masonry walls, the cover can be laid on a bed of stiff mortar and then blended with the tank as shown in Figure 14 below.
- The cover can be lifted into place by four strong people. Strong wire can be placed around the outer hoop where the cover was left un-rendered. Two strong timber poles can be placed through these wires. These poles are then lifted by four (or eight) people Alternatively two poles can be placed under the rim of the cover, but this makes it more difficult to set the cover down.
- Special care should be taken not twist the cover or put any undue stress on it as this could cause it to crack.
- If the tank wall is quite high then a raised platform should be constructed (from earth or timber) to stand on.

Figure 14. Blending the cover with the tank wall.

- A suitably sized ferrocement disc can be cast as the access hatch cover or another option used if so desired. This should be well fitting to prevent insects and contaminants entering the tank.

Tests for thin-shell, ferrocement tank cover

1. Point loading

The following load was applied with no adverse effect to the cover:

Figure 1 – Loading for point load test

Area of point load = 200 x 100mm = 20,000mm^2

Load applied 160 kg

i.e. 8kg / mm^2

2. Uniform loading

The cover was tested in two modes: constrained at the periphery to prevent slipping and unconstrained. In both cases the cover was loaded to approximately one thousand kg using house bricks (see Figure 4 below) and the deflection at the centre was less than 2mm in both cases, measured with a dial micrometer (Figure 3).

Figure 2 below shows the deflection against load for the constrained and unconstrained uniform loading.

Figure 2 – Deflection of thin-shell ferrocement cover under load a/ constrained at edge b/ unconstrained

Figure 3 – dial gauge in place to test deflection of cover under load

Figure 4 – Thin-shell cover under a load of 1000kg of bricks – an evenly distributed load

The mortar dome cover – guidelines for construction

(Taken form a DTU working by Terry Thomas, Ben McGeever and members of URDT, Uganda)

1. Introduction

The mortar dome cover was developed as part of a collaborative project between the Development Technology Unit and the Uganda Rural Development and Training Programme (URDT), Kampala, Uganda. The cover is being reported here as an example of very low-cost technology for Roofwater Harvesting. The cover was part of a design of tank for underground storage of rainwater. The cover is also suitable for use on above ground tanks.

The Cover is a dome of mortar (containing almost no reinforcement) connected to a reinforced 'ring beam' set into the ground. The mortar dome and the ring are made at the same time over a carefully shaped mound of earth. Set into the mound are a bucket and a large plastic bowl. The bucket is to create a way for the rainwater to enter. The bowl is to create a hole to hold the plug in which the pump is set. It has to be large enough (e.g. 0.45 meter diameter) for a man to enter through. The 5 steps in making the dome will now be explained in turn.

2. Construction steps

Step 1 - Making the 'template' for shaping the dome

The shape of the mortar dome comes from the shape of the mound of earth it is built on. We therefore need a template to accurately form that mound of earth. Before building the first tank it is necessary to cut this wooden template. Once made, the template becomes a tool that can be used for many more tanks. The template must be the right shape and also strong enough to carry around and use without getting broken. It therefore consists of a piece of plywood, or thin planks, cut to that shape and stiffened by strips of thicker wood.

The right shape for the dome is approximately a upwards 'catenary'. A downwards catenary is the shape taken by a chain hanging between two nails on a wall, so we mark the template out using such a chain (e.g. 1 or 2 lengths of bicycle chain) and then turn it upside down.

First cut the plywood so that it measures 125 cm by 100 cm and has square corners. Figure 3a shows 2 nails spaced 2.2 meters apart on a horizontal line drawn across a flat wall using a spirit level. Draw a vertical line down the wall from midway between these two nails and mark a short line (the 'mark') across it 80 cm below the horizontal line. Hang a light chain between the two outside nails and adjust its length until it just reaches down to this mark. (If you do not have enough chain to do this, see the alternative below.) Slide the thin plywood behind the chain without touching it, so that the long top of the plywood touches the left-hand nail and the right side of the plywood lies along the vertical line. With a pen, copy the shape of the hanging chain onto the plywood, remove the plywood from the wall and saw along the line you have just marked. (Using planks instead of plywood, first nail them rigidly to their

stiffening bar so that they can be placed behind the hanging chain; then continue as for plywood).

Although it is easiest to make the catenary with two bicycle chains joined end to end, it can also be done with only one. This has to be hung so that it forms just over half the full U-shaped catenary: one end of the chain is attached to the left-hand nail, the other end is held low and pulled until the lowest point of the chain falls exactly over the ‘mark’. You can now drive in another nail (‘alternative nail position’ in Figure 1) to attach the chain to, while you are copying the chain’s shape onto the plywood.

It is necessary that the chain has no twists and that it hangs freely, otherwise it might take up the wrong shape. The right shape ensures that the mortar dome is strong (by being everywhere ‘in compression’). Rope is not usually suitable instead of chain, because most ropes twist and are not heavy enough to hang properly.

To finish the template, stiffen it with good wooden strips. Now turn the template over so that the long straight side is on top and write the word ‘TOP’ next to it. Smooth the sharp corners to make it safer to carry.

Figure 1 Making the template

Figure 2 Forming the earth mound

Step 2 Marking out and making the trench and earth mound

The centre of the cover should be marked by a firm and vertical (use a spirit level) thin stake. Make a clear ink mark or cut a ring round the stake about 30 cm above the ground. Using a string 110 cm long looped once round the stake, mark out a circle of diameter 220 cm on the ground. This circle marks the inside edge of the trench in which the ring beam will be cast.

Dig a narrow trench (one hoe's width) outside this circle and throw some of the soil into the centre round the pole. The idea is to dig down 50 cm leaving a mound of firm soil inside the ring rising up to the ring round the stake. The shape can constantly be checked using the template - now with 'TOP' at the top - placed against the stake and rotated like a scraper. The template should be kept level by means of a spirit level and at the right height with its lower corner touching the ring marked on the stake. This is shown in Figure 2.

If the mound is rough or loose or fissured by drying, it can be plastered with more mud and wooden 'floated' to make it smooth and firm.

Chicken mesh can be fixed in the trench so that later on it can be used to improve the joint between the mortar lining the tank wall and the mortar of the ring beam. Make a single strip of mesh by cutting a 1.5 meter length into 5 strips each about 18 cm wide and twist joining them end to end - the final strip should be adjusted to fit round the inside face of the trench like a ring. This ring should now be folded longwise into the vee-shape shown in Figure 3 and the inside half buried in the earth of the dome. To do this you will have to cut out some earth from the inside of the trench, place the chicken mesh then plaster back the earth again.

The trench is now too wide for the ring beam, so fill back a step 10 cm high round its outside so that its bottom becomes only as wide as your foot - about 10 cm. (You will need to walk round this slot when you are plastering the dome). This too is shown in Figure 3. The bottom of the earth dome that faces into the trench should be grooved with a trowel or stick: these grooves will be ‘copied’ onto the inner edge of the ring beam and will later help ‘key’ the plaster joint to be formed there.

Finally place the bucket and the basin on the dome as shown in Figure 4. The bucket (the inlet) should be on the side nearest the house, with its edge touching the stake. The large basin (for the excavation access and later the pump hole) should be on the other side of the stake and with its edge 25 cm from the stake. Weight down the bucket and basin with stones and push them into the soil mound so that they do not rock; local excavation will allow the bucket to be sunk a desirable 20 cm into the soil. Put a small fillet of mud round each bowl as shown.

Pull out the stake without disturbing the mound.

Step 3 Preparing the reinforcing bars

Use 6 mm bar; it does not matter whether it is round or knobbly. Make a ring whose diameter is 230 cm, folding over and linking the ends and hammered the link tight so that there is no play in the joint. This ring will take about 8 meters of bar. Test that the ring will sit in the middle of trench without getting close to either its inner or outer edge.

Make two further such rings but much smaller, one each for the bucket and the bowl. Each ring should have a diameter bigger than its bucket/bowl so as to leave a clearance of 3 cm all round it where it enters the soil dome.

Step 4 Casting the ring beam and the pierced dome

The dome and the ring beam that forms its bottom edge are made of strong mortar in the manner shown in Figure 5. The mix is 1:3 (cement : sand) and 2 bags of cement should be ample. Concrete, mixed 1:4:2 (cement : sand : small sharp aggregate), is an alternative where such aggregate is available or can be made; a concrete dome needs only 1.5 bags of cement. (Concrete is more difficult to place as a plaster than is mortar and the surface finish achievable is not so good.) The ring beam is about 10 cm x 10 cm, while the rest of the dome is covered with 2 cm of mortar. However round the bucket and bowl this depth is increased locally to about 8 cm to make a good lip to hold the bucket/bowl and to cover the reinforcing rings there. As usual all three rings of reinforcing bar must be in the middle of the mortar with several centimetres of cover on all sides. So they must be placed as the mortaring progresses. The big ring, in the ring beam, is therefore placed only after 5 cm of mortar is already in the trench.

It is important to check the mortar thickness nowhere gets less than 2 cm as you work up the dome. There should be no joints in the mortar: the whole dome and ring beam should be made (plastered) in a single session with a mix that is dry enough not to slump. As the soil dome may suck water out of the mortar or concrete applied on top of it, it should be thoroughly wetted before plastering the dome starts. Moreover in a

hot climate it is wise to do this plastering early in the day so that the new dome can be covered with wet straw before the sun gets very hot.

Step 5 Curing the dome

As soon as the mortar is firm, gently remove the bucket and basin from the top of the dome.

Once the dome is cast it needs to cure under moist conditions for 14 days to develop a high strength. The simplest way to ensure it is kept moist is to cover it with plenty of grass and douse this with a jerrycan of water every morning and afternoon.

Report A3

Stabilised Soil Tanks for Rainwater Storage

Development Technology Unit

University of Warwick

Prepared by Mr. D.G. Rees

September 2000

This report is submitted as Milestone A5 under EU Contract ERB IC18 CT98 0276 : "Domestic Roofwater Harvesting in the Humid Tropics". That Milestone, under Task A – Technology, was originally to have been a report on the performance of underground tanks. Due to a re-sequencing of the research programme this Report A3 "Stabilised Soil Tanks for Rainwater Storage" has been substituted as the Milestone.

1. Introduction

The present cost of roofwater storage tanks is too high for many potential users. Warwick University, under an EU contract with three other partners, is investigating ways of reducing it within the specific context of the contract title above.

One cost-reduction strategy is to employ cheaper materials than hitherto. Soil 'as dug' is certainly cheaper than the metal, mortar or plastic commonly used for tank building. Stabilised soil *may* be cheaper provided not much stabilising additive is used. Although soil-based walling is widely used in housing, water tank walls pose special problems. They require of their materials two extra attributes, namely waterproofness and *tensile* strength that are only of minor importance in housing. Since soil is not impermeable and wet soil has no tensile strength, a process of material adaptation is required before soil can be recommended for tank construction.

Sections 2 to 4 of this paper review the various techniques of soil selection, stabilisation and construction. Section 4 addresses tank design using this material. Two promising technologies are identified, namely construction using stabilised soil blocks (SSB) and construction using stabilised or even unstabilised rammed earth (RE). Section 6 describes the theory, design, prototype manufacture and Ugandan field testing of SSB rainwater tanks. Section 7 covers the same sequence for RE tanks, but also includes the results of laboratory trials.

The paper finishes with conclusions and the identification of further work required to confirm the initial promise of SSB and RE construction. Four appendices cover cost comparisons, test data and detailed construction guidelines. (The guidelines are in the form of a free-standing Technical Release designed for use in mason training.)

Note on units: Both imperial (foot=0.3 m and inch=25 mm) and metric units are used in this report, reflecting the predominance of the former amongst builders in Equatorial countries and the greater ease of the latter for calculations.

2. Soil/earth building technology

Almost a third of the world's population lives in unbaked earth housing. The technology used varies from country to country and region to region, and sometimes even from house to house. A wide variety of earth construction technologies are known to exist and a few are listed below.

- Adobe – sun-baked earth bricks
- Wattle and daub – a wooden lattice with daubed earth in-fill
- Compressed earth blocks – using a ram (of which there are many designs)
- Direct shaping – hand shaped earth
- Cob – coarse fibre reinforced balls of earth stacked and compacted lightly
- Dug-out – dwellings excavated from earth
- Rammed earth – earth compacted between shutters with a tamper

Of these seven variants, only two appear at all suitable for constructing (above-ground) tanks, namely stabilised soil blocks and rammed earth.

Figure 2.1 Buildings (a clinic and a latrine under construction) made from stabilised soil blocks in Tanzania

All the technologies mentioned above are ancient techniques that have been passed on from generation to generation. Many have only lost favour within the last century with the advent of modern building materials, particularly brick, cement and steel. They are still used widely in many developing countries where cement is prohibitively expensive for the poorer sections of society (see the map in Figure 2.2). In some cases cement is used in small quantities to 'stabilise' the earth, giving extra strength and impermeability. Earth building technology is seeing something of a revival in the West amongst groups keen to maintain traditional techniques and those who appreciate the superior properties of earth as a building material e.g. its thermal, aesthetic, environmental and cost advantages. Improved techniques have been developed by architects and engineers over the years.

Stabilised soil block (SSB) technology that has received a great deal of attention over the last few decades and is now seen as a mature technology with a good future in the building industry world-wide. It is a technology particularly suited to drier climates, although it is practised in many humid areas. Suitable earth is mixed with a small percentage (typically 5 – 10%) of cement and is compacted using a manual or hydraulically assisted ram or press (Figure 2.3). The compaction process can be static (slow squeezing) or dynamic (impactive), but the static process is more common.

Static compaction pressure ranges from 2 MPa in manual lever machines up to 10MPa or more in machines with hydraulic assistance.

Figure 2.2 Map of the world showing areas where earth construction technologies are, or have been, widely used

Figure 2.3 A CinvaRam press being used to produce stabilised soil blocks in Africa

Rammed earth (RE) is a technique whereby earth is rammed, using a rammer or tamp, between two shutters. The shuttering is removed to reveal the wall, usually constructed in sections of a few feet long by a foot or two deep. The shuttering is then moved along and the next section of wall is rammed to form a continuous wall. The shuttering is then raised and placed on top of the first 'lift' to construct the subsequent

'lifts' (see Figure 2.4). Unlike SSB production, the RE wall is built in situ. Wall thickness for a typical two-storey house is in the region of 12 to 24 inches. Curved walls of rammed earth are not common, but are found occasionally where the technique is more developed. The curved sections are usually for decorative purposes.

Typically rammed earth has been used for the construction of housing. The technique has been used to successfully construct buildings of several stories that have lasted for centuries.

Figure 2.4 (i) rammed earth as practised in Morocco and (ii) basic elements of formwork or shuttering (from Norton[1997])

3. Soils - identification, classification and testing (field and laboratory methods)

3.1. Characteristics of soils

Not all soils are suitable for construction and methods have been developed for identifying those that are. For rammed earth (RE) construction a soil should be a mix of fine gravel, sand and silt with a small clay content. There should be no organic material present. Soil for stabilised soil block (SSB) construction needs to be of a higher fines content. However the actual soil used for either technique varies widely. Norton [1997] suggests the figures shown in Table 1 as suitable for rammed earth construction. The clay content should be sufficient to allow the soil to bind without causing excessive shrinkage. Soil varies widely in quality and content and so experimentation is required to find a suitable soil.

Table 3.1 – showing suitable values for soil particle distribution for rammed earth structures (Norton[1997])

Sand / fine gravel	45 – 75%
Fine sand / silt	15 – 30%
Clay	10 – 25%

Soil is generally characterised by 4 fundamental properties: texture, plasticity, compactibility and cohesion. These properties are described briefly below.

Determining the soil texture involves passing the material through a series of standard sieves and observing the fraction retained by each sieve, thus determining the grain size distribution. Further analysis is usually required to determine the fines content i.e. the make-up of the silt and clay passing through the finest practical (0.063 mm) sieve. Graph 3.1 shows the acceptable range for soil that is to be used for rammed earth structures. The ASTM-AFNOR standards and the decimal system standard for grain size distribution can be found on page 32 of Houben [1989].

Graph 3.1 Showing the acceptable particle distribution for a soil used for Rammed Earth construction (Houben [1989])

The Plasticity Index (PI) is an indicator of the plasticity of the soil. The PI is a function of the Liquid Limit (LL) and the Plastic Limit (PL) of the soil (together known as the Atterburg limits) and is a measure of the likelihood of the material to deform. LL is the % of water in a soil when it is changing from being 'plastic' to being 'liquid'. PL is the water % at the boundary between solid and plastic behaviour. Numerically PI = LL – PL. There are agreed definitions of these transition points. Figure 3.1 shows on an Atterburg limits chart the type of stabiliser to be used with any particular soil.

The **compactability** of a soil defines its ability to be compacted to a maximum for a given compaction energy and degree of humidity {Houben 1994}. The compactability of a soil is measured by the Proctor compaction test (see Section 3.3).

Cohesion is a measure of the ability of a rammed soil to remain together when under tensile load. Cohesion is a function of the moisture content and the clay content (or other cementitious material) of the soil. Cohesion is higher when the moisture content is less than the PL. Cohesion increases with clay content, but so unfortunately does shrinkage.

Figure 3.1 – The Atterburg limits chart (Norton[1997])

3.2. Soil suitable for rammed earth structures

A sieve analysis should indicate the ranges shown in Table 3.1 if a soil is to be used for earth construction.

Soil for use with rammed earth structures should be humid, i.e. not too dry and not too plastic, say in the region of 4% to 15% moisture content. The optimum moisture content (OMC) is defined later in this document and a method shown for determination of OMC.

3.3. Soil identification and classification

The suitability of a soil for building with is often established via three sorts of test – field tests, laboratory tests and construction trials.

Field tests

These are cheapest and come first. There are numerous initial sensory observations that can be made to help classify the soil in the field. These include:

- visual and tactile observation to analyse particle distribution
- sedimentation test to give more detailed particle distribution
- there are a number of tests to gauge (very roughly) clay content, including a simple test whereby a roll of clay is pushed over the edge of a table until it breaks - the length of the broken part gives an indication of the clay content
- drop test to determine optimum water content
- the smell of soil can sometimes give an indication of the presence of organic matter

More detail on these tests can be found in the relevant literature, especially Keable[1996], (Rammed Earth Structures – A Code of Practice).

Laboratory tests.
British Standard BS 1377 and corresponding standards in other countries cover the tests suitable for soils used in construction work. The tests are used to determine the main characteristics and suitability of the soil in question, as well as to give an initial idea of the performance of the material. The main tests that are used are described very briefly below:

A *'classification test'* is performed to determine the particle distribution of the soil. The test is carried out by passing the soil through a set of standard sieves (Figure 3.2). Material passing through the smallest sieve in the set is deemed to be a mix of clay and silt: these two components cannot be separated by further sieving.

Figure 3.2 – Wet sieving is the standard soil classification method

To determine the *'clay to silt ratio'*, the fraction of the soil passing through the last (0.063 mm) sieve is analysed using a hydrometer. The specific gravity of the liquid with its suspended particles, indicates its clay content. An alternative simpler test takes advantage of their different sedimentation rates to distinguish between clay and silt.

The compaction of a soil is dependent upon its moisture content. A *'compaction test'* is used to determine the maximum density of the material and the moisture content at which it occurs – called the optimum moisture content OMC. At maximum density the compressive strength of the soil will be greatest. To find the OMC a test is carried out using a simple compaction apparatus (see Proctor compaction test in Box 3.1) to compact a number of samples with different moisture contents. The samples are

weighed and measured. The dry weight is then found after drying the compacted sample in an oven and the OMC is that moisture content which has produced the sample of greatest density.

Box 3.1 BS Ordinary Test (or the Proctor test) for compaction

This test uses a 2.5kg metal rammer with a 50mm diameter face that falls into a cylindrical mould of 105mm diameter. The drop height is kept at a constant 300mm to ensure consistent energy transfer between blows. The blows follow a pattern over the face of the sample to ensure repeatability and consistent compaction of the entire sample. Each sample made up of three layers of soil that has passed through a 20mm sieve and each layer is given 27 blows of the rammer. After compaction the sample is trimmed off to a set height that gives a constant volume of 1000cm³. This is then weighed and the density can be calculated.

In the previous section we touched briefly on the consequences of shrinkage. The *'shrinkage box test'* measures this property and is simple to carry out. It involves measuring the shrinkage of a sample that is allowed to dry naturally over a period of 14 days. In practice, if the walls of a tank are constrained, say at the base, then cracking will take place if shrinkage is significant. Conversely, where a tank's cylindrical wall is free to shrink without constraint no cracking will take place. If shrinkage is found to be too great, due to an excess of clay, the soil will have to be either modified or rejected.

'Liquid and plastic limit tests' can be carried out either in the field, although it is preferably to perform them in a laboratory. Some equipment is needed. See section 3.1 for more detail.
A *'normal moisture content test'* is used to determine the normal moisture content of the material to be used. An oven and accurate scales is required.
To measure the rate at which water passes through a material requires a *'permeability test'*. Sophisticated equipment is required.
For many applications of rammed earth walls (i.e. housing and larger buildings), it is the compressive strength that should be maximised, so *'compressive strength tests'* are commonly applied to the material. *Wet* compressive strength, which is invariably less than *dry* compressive strength, is most commonly measured. Unfortunately little consideration is given to the *tensile* strength of the material which concerns us more in water tank design. Confusingly we have four possible strength measures: *dry compressive, wet compressive, dry tensile* and *wet tensile*.

Although Houben and Guillaud [1989] indicate reasonably good values for dry tensile strength of rammed earth (0.5 –1 MPa), little work has been directed at further increasing its value. For the application being considered here, the tensile strength of the material is of paramount importance. The OMC considered earlier is the moisture content that will optimise dry density (we could call this the DOMC , after Montgomery [1999]), and hence compressive strength. It is unclear to the author if this DOMC can be used to optimise dry tensile strength. Further investigation is required to find the water content to maximise dry tensile strength, which we could call the Tensile OMC (or TOMC). We then need to consider the wet tensile strength of the materials as this has great implications on the design of tanks to hold water.

Performance tests.
Even where we have applied field and laboratory tests to the raw material (soil) or to specimens prepared from it, it is still desirable to test samples of the walling during construction. In this way we can pick up not only soil variations but also imperfections in the construction process (such a deviations from intended proportions or procedures). These performance tests are usually applied either to samples drawn from batches in the construction process (e.g. every 50th block made) or to specimens sawn out of larger components.

Some of the tests that may be applied are:

- Wet and dry compressive strength
- Wet and dry tensile strength (modulus of rupture)
- Wet and dry bending strength
- Permeability
- Adhesion of render to walls

More details is available in the literature – see Houben

3.4. Calculating the quantity of soil required for a tank

The quantity of soil required for tank construction is calculated below. The quantity of soil required for tank construction is based on tank size, wall thickness and the density of the compacted material.

Weight of soil required $W = \pi (r_o^2 - r_i^2) H \times \rho_c$ (equation 2.1)

where
r_o = external radius of tank
r_I = internal radius of tank
H = height of tank
ρ_c = density of compacted material

For laboratory and development tests approximately 150 kg of soil is required.

4. Stabilisation of soils – methods for improving soil characteristics

Frequently one finds that the most readily available soil is not suitable for construction purposes. In such cases the main options are to

- bring in a suitable soil from elsewhere
- blend together different local soils
- add some sort of stabiliser.

Which option is chosen will usually depend upon their relative costs. However if wet strength is required, no natural soil is adequate and stabilisation (e.g. addition of cement) is essential. The physical characteristics of soil can be improved in a number of ways. Usually, the main reason to improve soil is either to obtain a suitable physical grading for a poor soil or to improve some other physical characteristic such as the strength, stability or water resistance of the soil.

Soil suitable for soil construction should be well graded with a suitable content of fines and larger particles (see Table 3.1). For raw soil, this is often not the case and soils have to be modified such that their grading is suitable for use. This will involve adding a material that is lacking in the raw material, removing unwanted particles by sieving or mixing a number of soils to obtain a suitable blend.

4.1. Additives and composite materials

A large number of additives and composites are available for adding to rammed earth. Their purpose is improve the properties of the material in one of a number of ways: *Chemical stabilisers* are added to the soil to bind or alter the grain distribution characteristics of the soil and hence improve its cohesion and stability. Common stabilisers include cement and lime, which are added in small quantities, say up to 10%, and can improve material strength and stability several fold. There is a wide range of synthetic additives available from specialist suppliers in some countries (Texas, USA is a good example, where earth building is a commonly practised building technique). They are not, however, generally available in developing countries and so we will not consider them in this work.

Waterproofing agents are available that reduce the permeability of soil structures. A commonly used water repellent is bitumen, which is mixed with the soil in an emulsion form. The emulsion is made using a solvent such as gasoline or kerosene diluted sufficiently to be mixed with the soil (Norton[1997]). Many synthetic waterproofing additives are available. Most earth walls, bearing in mind that such walls are used for buildings, are given a waterproof render, or a sacrificial coating. Renders and linings will be discussed later in the document.

Fibres can be added to increase the tensile strength of the material and help prevent cracking during the curing process. Straw is a common fibre additive and it also helps to reduce the weight of the material. Unfortunately it is only durable in permanently dry conditions.

Reinforcement is widely used to create a composite in which the matrix (e.g. soil) provides some properties and the reinforcement (e.g. steel wire or polypropylene or hessian rope) provides much of the tensile strength.

Box 4.1 Discussion of the effects of soil shrinkage on tank design, and design implications.

Upon drying a rammed earth wall will shrink as the moisture is drawn out of the structure and the clay, which is expansive (different clays having differing degrees of expansivity), shrinks. If the structure is constrained in any way, say for example, at the base of the tank, then this could result in cracking. For an unreinforced tank such cracking would seriously reduce tensile strength and could cause sudden and catastrophic failure of the structure. This needs to be considered when determining the OMC (or TOMC) and the author suggests that this area of rammed earth tank design needs further work at present. It is for this reason that some form of reinforcing could be used to give additional tensile (hoop) strength to the structure. Possible forms of reinforcement include:

- Externally applied steel packaging strap (as demonstrated by the author {Rees, 1999} on single skin brick tanks)
- Hoop wire rammed into the structure – ideally barbed wire would be used as it is cheap, strong and the barbs offer resistance to 'pull-through'.
- Fibre such as straw or short lengths of polypropylene rope can offer localised strengthening

Box 4.2 Stabilisation of soils (Montgomery[1999])

Stabilisation techniques can be broken down into three categories, Houben (1994): Mechanical, Physical and Chemical. Mechanical stabilisation compacts the soil, changing its density, mechanical strength, compressibility, permeability and porosity. Physical stabilisation changes the properties of the soil by acting on its texture, this can be done by: controlling the mixture of different grain fractions, heat treatment, drying or freezing and electrical treatment. Chemical stabilisation changes the properties of the soil by adding other materials or chemicals. This happens either by a physico-chemical reaction between the grains and the materials or added product, or by creating a matrix which binds or coats the grains.

Stabilisation fulfils a number of objectives that are necessary to achieve a lasting structure from locally available soil. Some of these are: better mechanical characteristics (leading to better wet and dry compressive strength), better cohesion between particles (reducing porosity which reduces changes in volume due to moisture fluctuations), and improved resistance to wind and rain erosion. Using one or more of the stabilisation techniques listed above, many of these objectives may be fulfilled. Optimum methods depend greatly on the type of soil, and a careful study of the local soil is necessary to suggest an effective method of stabilisation. In the case of mechanical stabilisation, the soil is compacted to a greater density, and there will always be an improvement in its mechanical properties with virtually any soil type. This is not true however with other forms of stabilisation, where different soil mixtures can lead to better or worse properties using the same technique. In the majority of cases mechanical stabilisation is used in conjunction with a common chemical stabiliser, such as cement. If the stabiliser and the soil are mixed together thoroughly and there is a suitable clay fraction in the soil, the compaction process reduces the quantity of chemical stabiliser required in the block. The increased density also increases the effectiveness of the cement matrix, given that the cement is left in a moist environment (the hydration period to let the cement cure) for at least 7-14 days. For details on selection of soils for cement stabilisation see Gooding (1993 - B).More details on the process of cement stabilisation can be found in Houben & Guillaud (1994) and Spence (1983).

http//:www.eng.warwick.ac.uk/DTU/buildingmaterials/index.html, 1999)

5. Tank design using stabilised soils

It is certainly inconvenient, and it can be dangerous, for a water tank to fail (because at some point in it the local stresses exceed that which the tank material can bear). We therefore need to be able to calculate the size and location of the peak stresses. Unlike

other areas of structural design, stretching does not need to worry us much unless it is severe enough to cause the cracking of a superficial waterproof coat.

Our general design objective is to produce a safe watertight tank. This we can do either by using a single walling material that is both strong (in tension) and waterproof or by combining a strong material with a waterproof one. A wall of unstabilised soil is not waterproof and (when wet) doesn't have any tensile strength either. We therefore have either to stabilise it or to keep it dry by applying a waterproof skin to its inside face. In the latter case we must allow for the possibility that the skin will be punctured during the life of the tank – including some sort of reinforcing that may not save the tank but will prevent it bursting suddenly and dangerously.

5.1. The theory of stresses in cylindrical tanks

Tall cylindrical tank walls experience a horizontal tensile 'hoop stress' which is proportional to the diameter *D* of the tank, the local pressure *p* on the walls of the tank and the thickness of the tank wall *t* (Equation 5.1). As *p* increases towards the bottom of the walls, so too does the hoop stress.

$$\sigma_t = \frac{pD}{2t} \qquad \text{(Equation 5.1)}$$

However the stress in a cylindrical tank wall near to its base is also be affected by the type of joint between the tank base and tank wall. There are two obvious cases to consider as illustrated in Figure 5.1 below. In Case 1, the tank wall is made so that is free to move slightly at its base and yet still maintain a watertight seal. The water pressure against the wall will cause the diameter of the tank to increase until the hoop stress is wholly taken up by tensile stretching of the wall. (In the figure the increase in diameter is exaggerated here for clarity: in practice it might be less than 1 mm). The maximum hoop stress will be experienced at the base of the wall and will decrease linearly with height to zero at the top of the wall.

a/ **Case 1** – walls free to move relative to base

b/ **Case 2** – Walls joined to base

Figure 5.1 – The two cases for wall-to-base union in cylindrical tanks

Figure 5.2 – Hoop stress in the tank wall for Case 1 (i.e. wall and base separate)

In Case 2, where the wall and base are monolithic i.e. the wall and base are continuous (and the base is assumed to be rigid), the situation becomes more complex. Bending and shear stresses are set up in the wall as a result of the restraining effect of the base slab. There now exists a combination of bending, shear and hoop stresses. The lower part of the wall is now constrained and is not free to move as in Case 1. The result is that a bending moment is generated in the wall that is a maximum at the joint of the wall and the base. This bending moment sets up vertical tensile stresses on the inner face of the wall of the tank that can be more than twice the magnitude of the horizontal hoop forces. Shear forces are also generated although these can generally be neglected as they are small in comparison the other induced forces. This is illustrated graphically in Figure 5.2

Figure 5.3 – Hoop stress for Case 2 (i.e. wall and base monolithic)
(D, H and t as in Figure 5.2)

Figure 5.4 – Bending moment induced in tank wall for Case 2
(D, H and t as in Figure 5.2)

In Figure 5.2 we see that for Case 1 the hoop stress increases linearly from zero at the top of the tank wall to a maximum of 0.098 MPa at the base/ wall joint

In Figure 5.3 we see that for that Case 2 the hoop stress is a maximum of 0.058 MPa – less than in Case 1 – and occurs at 0.8m from the base (i.e. 0.4H). The hoop stress then drops off to zero at the base where the strain is zero. In Figure 5.4 we see the effect of the rigid constraint on the bending moment that is now induced in the wall. The maximum vertical tensile stress in the bottom of the inner face of the tank wall in Case 2 is 0.16 MPa, considerably more than the maximum hoop stress in either Case 1 or Case 2. So the tank is now vulnerable to cracking at the wall-base joint.

5.2. Conclusions from Section 5.1 and implied design considerations when using soil as a building material

Note:
Case 1 - wall is free to move at base (flexible joint)
Case 2 - wall and base are continuous (monolithic joint)
(assuming rigid base in both cases)

Table 5.1 Summary of conclusions from Section 5.1 and resulting design implications

Conclusions from Section 5.1	Design Implication
In Case 2 a bending moment is set up in the wall due to the constraint at the base of the tank. This is a maximum at the joint of the wall and the base and causes vertical stresses whose size is more than twice the maximum hoop stress. No bending moment is induced in Case 1.	Sliding base / wall joint are preferable to avoid complex stress regimes in the tank walls (see Box 4.1 below). These are difficult to achieve in practice.

The vertical stress cause by bending is very sensitive to changes in wall thickness as it is proportional to $1/t^{2;}$ thus halving wall thickness will multiply stress by four. The hoop stress is only proportional to $1/t$.	Where a monolithic base / wall joint is used it is wise to use a good safety factor when considering wall thickness or to thicken the wall near the joint.
The maximum hoop stress for Case 2 is always less than that of Case 1 (for an identical tank profile) and is experienced at some point above the joint of the base and wall, typically 0.3H to 0.6H, but lower for very thin walled tanks.	Do not design the wall thickness to decrease with height in the case of monolithic tanks.
For a tank of identical profile, the maximum bending moment set up in Case 2 will be of greater magnitude than the hoop stress set up in Case 1 or Case 2 (see Figure 5.5).	A greater wall thickness is required for Case 2 than for Case 1. This implies more material usage and hence higher cost. On this point, it is worth bearing in mind that many materials will have a greater tensile strength than bending strength and so the problem will be compounded.
Deflection is greater for Case 1, as there is no constraint at the base to restrict movement of the wall.	Strengthening at the base can help reduce deflection for Case 1. This is important where renders are used to help prevent cracking due to excessive strain.

Figure 5.5 – The graph shows the relationship between hoop stress, maximum tensile stress due to bending and wall thickness. (*H* and *D* as for Figure 5.2) Note the significantly higher values for bending-induced tensile stress.

Box 5.1 Sliding / flexible base wall joints

Sliding of flexible joints between the wall and the base of a tank are common for large concrete storage. The reduction in stresses by using such a joint is well documented and the subsequent savings in materials well recognised. Such joints, in concrete structures, are usually effected using a bitumen layer between the base and the wall. The degree of movement in the wall is very small and the flexibility of the bitumen allows sufficient movement while maintaining impermeability.
The technique developed at the University of Warwick for work with soil tanks has been to lay two layers of polythene sheet beneath the wall of the tank. The sheets can have a smear of grease to help them slide across on another. The effect is to produce a 'sliding' joint that allows the wall and the base to act independently which, as pointed out in earlier, reduces stresses, simplifies tank design and leads to lower costs.

5.3. Spreadsheet design for rammed earth tanks

A spreadsheet has been developed at Warwick (Turner 1999) for aiding the design of cylindrical tanks. The spreadsheet allows the main variables to be entered and gives output in terms of design parameters. The main variables are tank diameter, tank height, material properties (or relative volumes in the case of composites), required safety factor and wall thickness. The outputs are given for both a tank with monolithic base and wall, and for a tank with separate base and wall. The outputs include maximum hoop stress, maximum bending moment, maximum deflection, maximum tensile stress on inside face of tank wall, maximum shear stress, tank volume and overall tank diameter. The spreadsheet allows the designer to play with the parameters until a satisfactory design solution is reached. Table 5.2 shows the general layout of the spreadsheet. The spreadsheet was used to design both the laboratory experimental tank and the field experimental tanks described and discussed in Section 7.

Table 5.2 Showing the input and output cells of the spreadsheet developed at Warwick to aid design of cylindrical tanks.

Data input section - click on boxes for data input instructions			
Parameter		**Value**	**Unit**
E (matrix)	e.g. soil	700	MPa
E (fibre)	e.g. steel	2.1E+5	MPa
po(matrix)		0.5	Poisson's ratio
po(fibre)		0.1	Poisson's ratio
thickness		0.20	m
tank rad		1	m
height		2	m
Vol. Fraction of fibre		0	0 – 1
po(total)		0.5	
E(total)		700	MPa
Volume		6.283	cubic metres

Output cells –for a Rammed Earth tank The output here is for a tank monolithic with base		
Tensile strength (of soil)	0.50	MPa
Safety factor required	4.00	
So design stress is	0.1250	MPa
Maximum hoop stress generated	0.0579	MPa
Position of max hoop force		m from base
Maximum bending moment	1069	Nm (always at base)
Maximum deflection	0.0033	mm
Position of maximum deflection		m from base
Maximum tensile stress on inner face of wall	0.16037	MPa (always at base)
Maximum shear stress	0.00021	MPa
Overall tank diameter	2.4	m

Output here is for tank wall unconstrained at base		
Tensile strength	0.50	MPa
Safety factor required	4.00	
Design stress	0.1250	MPa
Maximum hoop stress generated	0.098	MPa
Maximum deflection	0.1401	mm
No bending moment generated		

5.4. Construction principles when building with earth

There are several basic rules to follow when building with earth:

- The wall should be well protected from damp or wetness. Wet earth has less strength than dry and unstabilised earth will quickly become a mess of mud should it become saturated.
- Good foundations are used to protect the base of the wall from rising damp and often the first foot or two of wall above the foundation will be from stone or other impermeable material.
- Where a roof is fitted, the wall can be protected by using large overhanging eaves to prevent rain from hitting the wall directly.
- Renders or other coatings help to protect the wall from rain also. Practitioners colloquially use the phrase “good hat and boots” to describe the protection required – an overcoat doesn’t go amiss either!

The benefits of using earth as the construction material are numerous:

- low material cost (see cost comparison with ferrocement in Section 8)
- suitable material readily accessible locally in many parts of the world
- a well-known and widely-used technology in many parts of the world
- a simple technology that is easily taught to semi-skilled people

The drawbacks of using earth for tank construction are:

- not suitable for below-ground tanks or cisterns
- in the case of leaks serious problems can develop, especially if unstabilised earth is used
- high labour input – a problem where labour costs are higher

6. Stabilised soil block (SSB) tanks

6.1. Introduction

The work carried out on Stabilised Soil Block (SSB) tanks has been done in conjunction with Dr Moses Musaazi, a lecturer at Makerere University, Kampala and private entrepreneur working in the construction industry. Dr Musaazi also directs the Gatsby Trust in Uganda whose aim is to promote small-scale private enterprise through training. He has been working with SSB's for some time, both for low-cost housing and also for the construction of small too medium sized domestic rainwater storage tanks. Warwick University approached Mr Musaazi with the aim of working together to test the strength of the SSB tanks through practical experimentation.

A full report of the work that has been completed by Dr Musaazi is found in Appendix II.

6.2. The basic principles of SSB manufacture and construction

Stabilised, compacted, soil block technology is mature and widely used throughout the world. It involves compacting a suitable soil, which is often mixed with a small percentage (typically 5 – 10%) of cement, using a manual or hydraulically assisted ram or press. The compaction process can be static or dynamic, but the static process is most common. Static compaction pressure ranges from 2MPa (manual) up to 10MPa or more (hydraulic). This compaction reduces the voids in the material and hence it susceptibility to attack from water. Figure 2.3 shows a CinvaRam press being used on a building programme in Tanzania. Figure 6.1 shows some common press types.

Figure 6.1 – A small selection of the many press types available for purchase (Houben[1994])

Special moulds can be manufactured to produce blocks required for special purposes. In the case of the cylindrical tanks manufactured in Uganda, curved blocks were produced using the mould shown in Figure 6.2.

(**Figure 6.2** – Mould for producing curved blocks)

(**Figure 6.3** – Curved blocks after curing)

For information about tank linings and water extraction for SSB tanks see Section 7.2. These principles are the same for RE and SSB tanks.

6.3. Field testing of SSB tanks in Uganda

Tests on SSB tanks started in March 2000 in Kampala. A small cylindrical tank (1.0m internal diameter, 2.1m height) was built and an attempt made to fit sealed covers to it. The tank was to have been pressurised by means of a header pipe fitted to the cover, however this proved impractical so it was simply subjected to the pressure (21 kPa) derived from its own height. The materials used are specified in the report in Appendix II. The soil used was stabilised with 5.25% OPC.

The experimental method was changed for subsequent tests and two tanks were built of the same curved end-interlocked SSBs. No reinforcing was included, but the tanks were rendered inside with a waterproof mortar. Details are:

Tank diameter (internal) in m	Tank Height in m	Code	% cement
1.67	3.8	SST1	5.25
1.00	5.2	SST2	3.27

SST1 was tested in July 2000 and failed dramatically when only part full. SST2 is still under test.

(**Figure 6.4** – A SSB tank of 1.67m diameter)

SST1, according to theory and using the *dry* tensile strength for the blocks from the literature, should have been able to withstand about 5 times the stress induced by the water pressure at which it burst (at 2.5m water pressure). There were, however, some irregularities:

- Some of the blocks analysed after the experiment seemed to have no wet strength and disintegrated completely in water.
- The tank was filled from a large water tanker. The waterproofing agent that was used in the cement render lining takes time to act and so water would have been passing through the tank lining and into the soil matrix. This would have reduced the strength to somewhere below the dry strength quoted in the literature.

SST2 by contrast was filled slowly by rainwater from a gutter and has sustained a pressure, 53 kPa corresponding to its full height, for many weeks despite being built with considerably less cement in the blocks than SST1. The peak stress in SST2 is 50% greater than that at which SST1 failed.

A further complication in the analysis of any tank made of blocks or bricks is uncertainty about how tensile forces travel from one block to the next. One route is via the mortar that separates blocks of the same course. Mortar does not have very high adhesion to blocks, although in this case the loose interlock between block ends would have provided some shear connection. The other route is via shear forces into, and then back out of, the overlapping blocks in the courses above and below the course of interest.

Three further but smaller SSB tanks have been built and sold.

6.4. Conclusions concerning SSB tanks

It is unclear exactly what was the failure mode of SST1. It appears that the lining was not sufficiently waterproof to prevent water passing to the stabilised soil matrix, causing the soil to rely solely on its wet strength. The maximum stress induced in the wall of the tank at 2.5m water pressure is 0.234 MPa. This is the maximum resultant tensile stress on the inner face of the tank wall due to both bending and hoop stresses (as calculated using spreadsheet by Turner [1999]).

If we look at Graph 6.1 we see that the 7-day wet compressive strength for the material (which has a 5.25% cement content and was compacted at about 2MPa, is about 1MPa. Similar figures are found in Houben for 28 day wet compressive strength – see Table 6.1. The usual rule of thumb for dry to wet strength ratio for soil is 5:1. So we see that the wet strength of the soil blocks would be in the region of 0.2 MPa, which is lower than the induced stress prior to failure. It could therefore be said that the tank performed better than might be expected.

Graph 6.1 Graph showing variation of 7-day wet compressive strength with cement content for a number of compaction pressures (Gooding [1993]).
Cement content = 5.25% in our case.

So for this diameter tank (1.67m), using the construction method outlined in Appendix V, and with the standard 2.2m height, the dry strength would give a safety factor of approximately 5. However, if the tank lining should fail, or if the tank should become saturated for any other reason, then the tank would be on the border of failure as the wet strength (~0.2MPa) is approximately equal to the induced stress (0.2026MPa).

Table 6.1 Compressive and tensile strengths for SSB's. All the above assume 2MPa compaction pressure an assume tensile strength to 0.2 x compressive strength

Source	Compressive strength	Estimated tensile strength
Gooding (see Graph 6.1)	1MPa (7 day wet)	0.2MPa
Houben	1 – 2MPa (28 day wet)	0.2 – 0.4MPa (estimated by author)
Houben	5 – 12 MPa (28 day dry)	1.0 – 2.4MPa (estimated by author)

The analysis above would hold if the subsequent tests on the SSB's from the tank debris had not shown that some of the blocks had NO wet strength. The only explanation for this is that these blocks failed before their minimum strength was reached.

6.5. Further work with SSB tanks

Further suggested work on this area of work includes the following:
full laboratory analysis of the soil (the soil used in Kampala was somewhat pozzolanic and was assumed to be superior to standard lateritic soil there)

- development tests to determine the soil / block performance (however there is some suspicion that the blocks in SST1 had been starved of their proper cement allocation)
- further full-scale tank tests with some modifications to improve tank performance
- investigate methods for improving tensile strength e.g. reinforcing with barbed wire
- further work to investigate the relationship between wet and dry tensile strength of stabilised soils

7. Rammed earth (RE) tanks

7.1. Introduction to RE tank development

The general aims of the work carried out on rammed earth tanks (RE) are listed below:

- to set out the theory of RE tank design and to investigate the options available for RE construction
- to develop the specification for an experimental laboratory tank and two experimental field tanks
- to develop the skills required (within the research team) to analyse soils for building, in both the laboratory and in the field
- to investigate soil modification techniques and methods to develop a soil suitable for tank construction
- to develop the tools and equipment required for RE tank construction

- to develop a technique suitable for rammed earth tank construction
- to develop a technique for tank lining using plastic sheet
- to test a rammed earth tank under laboratory conditions to verify the theory
- to build a number of tanks in the field to test the feasibility of the technology and its suitability to LDC skills
- to test a tank under field conditions, again to verify the theory
- to carry out a cost analysis of a RE tank to allow comparison with other tank types
- to develop guidelines for the manufacture of RE tanks

Three (3) RE tanks have, to date, been designed and constructed:

- A tank of 1.4m diameter and 1m height was built at the University (RE-UK*). The tank was from unstabilised soil. The aim was to test the general principle of construction and to allow for initial tests to be carried out on earth tanks. The tank was completed in May 2000 and simple tests carried out, but full tests are yet be to be carried out on this tank. The simple tests include; fitting experimental linings, applying steel strapping and filling the tank a number of times to test strength. The full tests are to include a pressure test to ascertain the actual strength of the tank and to allow comparison with the theory.
- Two tanks of stabilised soil of 2m diameter and 2m height were constructed at Kyera Farm, Mbarara in June and July 2000. The first (RE1*) was constructed to a high specification (see Section 6.4.2) with concrete base and masonry wall section to 0.35m high. The second (RE2*) was designed to be very low cost using predominantly stabilised earth. Both were stabilised with 4% cement and reinforced with barbed wire hoops at 75mm intervals (see Appendix IV for Rammed Earth Tank Construction Guidelines)

** Note:*
For easy identification of the three tanks, they have been labelled as follows

RE-UK	- UK built tank
RE1	- Uganda high specification tank
RE2	- Uganda low specification tank

7.2. The basic principles of rammed earth construction

The general principles for building with earth are outlined in Section 5.4. and a full account of the rammed earth construction process used for the experimental tanks in Uganda is given in Appendix IV.

Some other points regarding RE construction are listed below:

- Availability of suitable materials is a key factor. If significant work is required in modifying the soil once it has been excavated, then the process can quickly become too costly.
- Wall thickness tends to be high, compared with modern materials. This is due to the relatively low compressive strength of the material and the variability in material quality. Compressive strength can be improved by using a small percentage (say 5% – 8% by weight) of cement mixed with the earth.

- Tensile strength is fairly low – in the region of 0.5 – 2.0 Mpa. The tensile strength can be improved by adding fibre or composite materials as well as by stabilisation with cement.
- The technique is characterised by high labour input and low material costs. This is well suited to many developing countries where labour is cheap and manufactured materials are costly.

The tools required for rammed earth construction can be few and of relatively low cost. In the West, sophisticated tooling has been developed, and sometimes costly pneumatic rams are used with steel shuttering, but in the less developed countries (LDCs) the tools have remained unchanged for centuries. Many designs of wood shuttering have been developed to meet the needs of the builder, but the principle actually varies little world-wide.

Figure 7.1 – Common types of shuttering used for RE construction (Houben[1994])

7.3. Equipment for making cylindrical RE tanks

Shuttering Most shuttering used for RE construction is designed to be used for the construction of straight walls. There are few examples of shuttering for curved walls, and those shown in the literature seemed to be unsuitable for cylindrical tank construction. The shuttering was, therefore, designed by the author and manufactured at the University workshops (RE-UK) and by local carpenters (RE1 and RE2) - see Figures 7.2 and 7.3. The UK shuttering required some subsequent strengthening to prevent deflection when compaction was taking place. The second set of shuttering was suitably strengthened during manufacture.

- *Shuttering fabrication methods used in UK*

The materials and techniques used for the shuttering construction varied slightly between the UK and Uganda. In the West, plywood is readily available, whereas in Uganda it is not. Plywood is well suited to forming curved surfaces through lamination and so 4mm plywood sheets were used to form the curved faces of the

mould – 3 layers glued together. Plywood (12mm – doubled up) was also used to form the main strengthening spines of the shuttering. The tie rods were from 12mm steel rod with T's welded on one end and threaded to sufficient length on the other. The nuts used were fitted with wings to make shuttering assembly easier. The end-stops were made for 12mm ply. The shuttering is shown in Figure 7.3.

Figure 7.2 – Common types of rammers used for RE construction (Houben[1994])

- *Shuttering fabrication method used in Uganda*

In Uganda sawn hardwood timber is more commonly available and this was used for the construction of the shuttering. The curved faces of the mould were made using 25mm x 25mm strips of timber butted to one another and glued and nailed carefully to

each other and to the main spines. The spines and end-stops were from hardwood. The work was carried out at a local workshop and needed constant supervision to ensure that the work was done in accordance with the drawings. The workshop had few power tools and most of the work was done by hand. Again, the tie rods were of 12mm steel rod with T's and threaded section. The shuttering is shown in Figure 7.4. Design drawings for the shuttering are shown in Appendix V.

Figure 7.3 – Shuttering manufactured in the UK

Figure 7.4 Shuttering manufactured in Uganda

- *Test for shuttering strength*

The standard test for strength of shuttering is that the mid point deflection of the shuttering, when loaded with a 150 kg weight (e.g. 3 bags of cement) should less than 3mm. Loading is mid point between the vertical stays.

- *Expected useful life of Shuttering*

Based on the experience in Uganda, where the shuttering was used to make two tanks, it is estimated that well-made shuttering should be good for the construction of

between 15 and 20 tanks, with some maintenance required to repair any damage caused during ramming.

Rammers / tampers The tampers were manufactured at the University workshops and at a local workshop in Uganda. Drawings are shown in Appendix V. The handles were of hollow round section steel in order that the weight of the rammer can be adjusted by partially filling the handle with sand. The profiled 'V' rammer, used for creating a joint that helps prevent shear, was made using a piece of 50mm angle iron welded to the flat base of the rammer.

Covers The DTU ferrocement thin-shell cover was used on both RE1 and RE2 and a special sealed (pressure-resistant) cover is to be developed for RE-UK.

Tank linings
Experiments have been carried out with two types of tank lining:

- *Plastic lining*. Work on plastic linings has been underway for some time at the University by an MSc student. A technique has been developed for welding 250 micron construction or damp proof membrane (DPM) plastic sheet to make 'bags' (similar to large bin liners) that fit inside the tank structure to form a waterproof lining. The welding technique has been successfully developed but there are still problems to be overcome in relation to the quality of 'off-the-shelf' plastic sheet and failure of the lining due to abrasion.
- *Cement render lining with waterproofing agent*. This is a more traditional form of waterproofing for water storage tanks and was eventually used for both the field experimental tanks. Further investigation into the nature of render linings, with particular respect to permeability and the effects of waterproofing agents, is underway at the University.

7.4. Laboratory work on RE tanks

Aims of the laboratory experiments Between November 1999 and May 2000 laboratory tests were carried out at the University of Warwick. The work was carried out to allow the author to gain experience with earth building technology and to develop a technique suitable for building tanks from soil. The full aims of the work was as follows:

- to set out the theory of RE tank design and to investigate the options available for rammed earth tank construction
- to develop the skills required (within the research team) to analyse soils for building, in both the laboratory and in the field
- to investigate soil modification techniques and methods to develop a soil suitable for tank construction
- to develop the tools and equipment required for RE tank construction
- to develop a technique suitable for rammed earth tank construction
- to develop a technique for tank lining using plastic sheet
- to test a rammed earth tank under laboratory conditions to verify the theory with regard to:
    - hoop strength (reinforced and un-reinforced)
    - the effect of rain on stabilised soil
    - performance tests for soil:

- wet and dry tensile strength
- wet and dry bending strength
- wet and dry shear strength (all three to be carried out at experimental and applied levels)
- swell and shrinkage
- erosion
- abrasion
- passage of water
- compatibility (adhesion) with renders and mortars

Preparation for the laboratory experiments The test site was established in a disused water turbine testing sump in the university laboratory. The set up for the experiments was time consuming and the preparation of the site took several weeks, mainly fitting lighting and safety equipment to conform with university safety regulations

Figure 7.5 Showing tank test area at the university laboratory

Desk work to develop experimental tank specification
Sufficient deskwork was undertaken to formulate a specification for the RE tank. The theory of stresses in tanks is given in Section 4 along with detail of the spreadsheet used to analyse stresses and to develop the specification for the experimental tank. The specification is as given below:

Table 7.1 Specification for laboratory experimental tank

Tank internal diameter	1.40m
Depth	1.0m
Wall thickness	0.1m

Wall / base joint	'slippery' joint using plastic sheet
Section bonding	Polypropylene knotted rope to give tensile bond for vertical joints V channel ramming for better horizontal joints
Drying time	2 weeks in dry environment

Work carried out in the laboratory

Soil analysis What was thought to be a suitable soil was purchased from a local quarry and an analysis was carried out. The soil is known locally as 'Hoggin'The soil was analysed using the standard wet sieving technique and the following results were obtained:

Table 7.2 Soil classification for Hoggin from Husbands Bosworth, UK, December 1999. Sample size 1500g, oven dried for 24hrs, wet sieved

Sieve Size (mm)	Weight retained	% retained	Description
20.000	220.6	14.87	Pebbles
6.300	394.6	26.59	Gravel
2.000	379.8	25.60	Gravel
0.420	222.5	15.00	Coarse sand
0.063	146.3	9.86	Fine sand
<0.063	120.0	8.09	Silt, fine silt and clay

Table 7.3 Results of a sedimentation test carried out on particles passing through 0.063mm sieve (from Table 7.2 above).

Time elapsed since agitation	Settled depth (mm)	% of total settled depth	Description	%age of total soil sample
1min	18	56.25	Sand	18.46
30 min	25	21.875	Silt	7.18
24 hrs	32	21.875	Clay	7.18

The soil was assessed and it was noted that:

a) there were many large stones >30mm
b) there was an excessive amount of material over 6.3mm in size – about 40% of total
c) there was insufficient clay for binding the material (7.18% of total material content)
d) there was insufficient sand in the soil

Soil modification It was decided that the soil should be modified. Several experiments were carried out to formulate a suitable soil and the following procedure was developed to prepare the required soil:

a) all large stones >30mm were removed
b) the soil was sieved to remove all particles above 10mm
c) the soil was then sieved again to isolate all particles between 5mm and 10mm
d) kaolin (china clay) was purchased and used to make up the deficiency in clay content

e) concrete sand was acquired to make up the deficiency in sand in the original soil

The final mix was as follows:

Hoggin <5mm	- 30%
Hoggin 5mm – 10mm	- 20%
Concrete (builders) sand	- 35%
Kaolin	- 15%

No stabilisation was carried out at this point and the material could therefore be recycled during the early tests.

Table 7.4 The sieve analysis for the modified soil (now known as Soil 4)

Sieve Size (mm)	Weight retained	%age retained	Description
6.300	83.80	9.16	Coarse gravel
2.000	232.10	25.37	Gravel
0.420	274.45	30.00	Coarse Sand
0.063	160.70	17.57	Fine sand
<0.063	163.80	17.90	Silt and clay

Soil 4 was used for all subsequent construction work in the laboratory.

Compaction tests and Optimum Moisture Content Compaction tests were carried out (as described in Section 3.3.2) on Soil 4 to determine the Optimum Moisture Content (OMC). The results show a moisture content of 9% to be optimum. However, in practice a figure of 8% was used as soil with 9% moisture content was too 'sticky' and caused the soil to stick to the rammers.

Liquid limit and plastic limit tests – the Atterburg chart Tests to determine the liquid and plastic limits were carried out and the results shown below:

Table 7.5 – LL, PL and PI Figures

Liquid limit	14.80
Plastic limit	9.59
Plasticity Index	5.21

Figure 7.6 – Early experimentation with ramming wall sections

Initial ramming tests and developing the technique for RE tank construction The shuttering was developed in such a way that 3 sizes of wall thickness could be tried; 60mm, 80mm and 100mm. The reason for this was that it was doubtful if the smaller wall thickness (the lower lifts) would withstand the compaction blows of subsequent lifts.

Early tests showed a number of problems with the ramming technique:

- the shuttering was deflecting and causing the wall section geometry to loose its true curvature
- the 60mm thick wall showed signs of cracking when the shuttering was clamped to it for the subsequent section
- when ramming, a reaction caused the shuttering to bounce or lift slightly (see Figure 7.7)
- the geometry of the shuttering was crucial and problems were encountered due to slight irregularities in the geometry

These problems were overcome by some adjustments to the shuttering:

- strengthening was added to prevent deflection
- the wider setting was used to produce a wall of 100mm thickness
- radial arms were fitted to the shuttering to maintain centrality and to allow weights to be added to prevent 'bouncing' (see Figure 7.7)
- the geometry of the shuttering was corrected slightly as no allowance had been made for the width of the end stops

The ramming force, F1, causes a reaction in the shuttering, R1, which causes the shuttering to lift and hence cause deformation. The weight, W1 (two x 25kg bags of sand were used), counteracts R1 and prevents the deformation.

Figure 7.7 Showing the forces created through ramming and the measures taken to counteract these forces

Manufacture of experimental tank A tank of 1.4m diameter and 0.7m height was built in a disused turbine testing sump (see specification given in Section 6.3.3). The tank was built from Soil 4. The aim was to test the general principle of construction and to allow for initial tests to be carried out on earth tanks. The tank was completed in May 2000 and simple tests carried out, but full tests are yet be to be carried out on this tank The simple tests include fitting experimental linings, applying steel strapping and filling the tank a number of times to test strength. The fuller tests are to include pressure tests to ascertain the actual strength of the tank to allow comparison with the theory.

Figure 7.8 Showing the experimental tank in the sump at the university

Composite materials for added tensile strength Composite materials and reinforcement can be used to improve the strength of compacted soil. For improved tensile strength the added material should have good tensile properties and be malleable so that it can be rammed into the soil matrix. Some ideal materials include barbed wire, polypropylene fibre and straw.

External reinforcement for added tensile strength External reinforcement such as steel packaging strap, barbed wire, or plain fencing wire can be wrapped around the finished tank walls for added tensile strength.

Laboratory tests Due to time constraints and unforeseen problems with developing the technique for RE tanks, other planned laboratory tests have not yet been carried out. Tests are being undertaken at present to verify the theory with regard to:
hoop strength (reinforced and un-reinforced)
the effect of rain on stabilised soil

- performance tests for soil:
- wet and dry tensile strength
- wet and dry bending strength
- wet and dry shear strength (all three to be carried out at experimental and applied levels)
- swell and shrinkage
- erosion
- abrasion

- passage of water
- compatibility (adhesion) with renders and mortars

This work will be reported at a later date.

Conclusions and discussion concerning laboratory work on RE tanks Soil analysis was carried out for a locally sourced soil. The soil was modified to create a suitable soil for RE tank construction. The tools and techniques for RE tank construction have been developed.

Developing the technique for RE tanks proved to be more problematic and time-consuming than was originally thought, with much work needed to overcome geometry problems. The level of accuracy required, both in shutter manufacture and in the construction process, is higher than expected. Early tests show that the RE tank design has good potential.

Soil preparation time is high and so a suitable soil should be sought in the field that requires little preparation.

The problems encountered during the construction process meant that few further tests have yet been carried out.

Further laboratory work
Recommended further work is listed below:
- Manufacture of sealed cover and tank pressurisation equipment
- Pressure testing of the existing experimental tank
- Data logging to allow analysis of the stresses in the tank during pressurisation
- Performance tests to analyse the soils characteristics in use
- Experiments to determine the effects of cement content on stabilisation
- Experiments to determine the effect of cyclic loading on rammed earth tank walls (cracking, joint failure, etc.)
- Waterproof lining (resistance to penetration, fixing methods, liner penetration for off-take, etc)
- Wet strength tests of tanks

7.5. Field work

The principal aims of the field tests were:
- to test the technique developed in the laboratory for rammed earth tank construction
- to test the technique for tank lining using plastic sheet
- to build a number of tanks to test the feasibility of the technology and its suitability to LDC skills
- to test a tank under field conditions to verify the theory
- to carry out a full cost analysis of a RE tank to allow comparison with other tank types

Specification for 2 experimental field tanks

The specification for the two rammed earth tanks is given in the tables below. The specifications were drawn up using the results of the spread sheet analysis and with the specific aim of testing a) a tank using standard building guidelines for rammed earth construction (RE1) and b) a low-cost tank using predominantly stabilised earth and minimising the cement content (RE2).

High Specification RE Tank (RE1)

Tank internal diameter	2.0m
Tank external diameter	2.4m
Tank height	2.0m
Tank capacity	approximately 6 cubic metres
Concrete base thickness	100mm un-reinforced (on 100mm hardcore where ground is soft)
Concrete base diameter	2.8m
Soil wall thickness	0.2m
Soil make-up	10% clay, 15 – 30% silt, 50 – 70% sand, 10 – 20% garvel, 4% cement stabilisation
Reinforcement	barbed wire hoops at 50-60mm spacing in rammed earth sections steel reinforced cement hoops at spacing shown in drawing
Lower wall dimensions	350mm stone masonry, 0.2m thickness
Tank lining	waterproof render approx. 15mm thick (or plastic liner)
Cover	thin shell ferrocement cover
Water extraction	By gravity – washout also by gravity

Low Specification RE Tank (RE2)

Tank internal diameter	2.0m
Tank external diameter	2.4m
Tank height	2.0m
Tank capacity	approximately 6 cubic metres
Base	100mm stone with 50mm compacted stabilised soil, 2.8m diameter
Wall	Stabilised soil, 0.2m thickness
Reinforcement	barbed wire hoops at 50-60mm spacing in rammed earth sections
Soil make-up	10% clay, 15 – 30% silt, 50 – 70% sand, 10 – 20% garvel, 4% cement stabilisation
Tank lining	plastic liner
Cover	thin shell ferrocement cover
Water extraction	by handpump where plastic liner is used

Some of the design features and design considerations that were incorporated are outlined below:

- The wall sections were given a ‘V’ profile to prevent shear. The aim was to encourage better bonding and so reduce the likelihood of shear. The profile was achieved using a special ram with a V attached. See Figure 7.9.

Figure 7.9 – Profile of the joint between 'lifts'

- The principle adopted for house construction of good protection at the base and overhanging eaves for protection from above were adopted, especially in the case of RE1
- The tank size is based on useful capacity and available catchment area
- Minimal cost – the general aim of this task is to reduce the cost of storage for rainwater
- The use of local materials as far as possible
- Durability – a minimum of 10 - 15 years life expectancy
- Easily constructed by local artisans in developing countries
- Foundations – these should be:
  - should be laid in a good sound soil
  - be protected against ingress of moisture
  - be protected against frost (not an issue in the Trpoics0
  - be protected from wind erosion – sand blasting in severe storms
  - be protected against animals, rodents, insects, etc
- Protection from surface water through good drainage (Houben pg 252) – ground to slope away from tank, ground gutters, moisture barriers,
- Foundations in unstable soils need to be considered – ground stabilisation may be needed

Work carried out in the field

The two tanks specified in the previous section were constructed at Kyera Farm. The procedure for their construction is outlined in Appendix IV. Each step of the work was carefully observed and monitored against the aims set out in Section 6.4.1. An initial field soil analysis was carried out to determine a suitable soil. Some modification was needed and then a full laboratory analysis was carried out on the modified soil.

Tests carried out in the field

Soil analysis – field tests

Three soils were analysed crudely in the field. The following tests were performed:

Sensory tests

The soil was analysed by feel, look and smell to test for initial suitability

Sedimentation test. The results are shown below:

Table 7.6 Results of the sedimentation test carried out in the field

Soil source	Soil code	T1	T2	T3	% sand	% silt	% clay
Murram from farm <4mm	S1	40	42.5	42.5	94	6	0
Anthill P <4mm	S2	22	53	53	37.7	62.3	0
RE2 excavation site <4mm	S3	53	59	59	89.8	10.2	0

Notes:
T1 = reading taken in mm, start time plus 1minute
T2 = reading taken in mm, start time plus 30 minutes
T3 = reading taken in mm, start time plus 24 hours
The murram has some organic material; good distinction between layers.
Anthill has little organic matter; poor distinction due to uniform colour.
RE2 excavation site high organic content; good definition.
Clay content is shown as 0% in each of the above. This is because further settling of the sand and silt after initial measurement caused final reading to be low.

A further sedimentation test was carried out to estimate the clay content. Tests were carried out on the murram and the anthill soil. Soil passing through a 0.075mm sieve was sedimented and readings taken at 20mins, 24hrs and 48hrs. From the readings obtained, the clay content was estimated to be:

Table 7.7 Results of tests to determine clay content of soils

Soil	Clay content	Comment
Murram from farm <0.075mm	4%	Again definition was difficult and the reading was not fully trustworthy
Anthill P <0.075mm	0%	Settling took place rapidly indicating little or no clay content

Soil modification

None of the three soils tested was fully suited to RE construction. However it was found that by mixing the larger particles of the murram (those retained on a 4mm sieve) with the crushed anthill soil, a suitable soil was developed. Stabilisation was provided by adding 4% cement. The cement percentage was kept deliberately low to save on cost. The final mix is shown in Table 6.8.

Table 7.8 Showing mix used for modified soil for RE tank construction

Material	Quantity
Crushed anthill soil	80%
Murram >4mm	16%
Cement	4%
Water	Added in sufficient quantity and checked using field test

Soil analysis – laboratory tests

An analysis of the modified soil was carried out at the Central Materials Laboratory, Ministry of Works and Housing, Kampala. The analysis is summarised below.

- *Sieve analysis*
  The full analysis is shown in Appendix III but a summary is given in Table 6.9

Table 6.9 Summary of sieve analysis for RE1 and RE2 tank soil

Classification	
Pebbles	0%
Gravel	21%
Coarse sand	17%
Fine sand	17%
Silts	10%
Fine silts	19%
Clays	16%

- *Other tests*

Table 7.10 Results from laboratory tests for construction soil

Test name	Testing for	Result
Hydrometer analysis	Specific gravity	Gs 2.65 (measured)
Atterburg limits(1)	Liquid limit	34
	Plastic limit	16
	Plasticity index	18
Normal moisture content	Normal moisture content	2%
Compaction and OMC(2)	Material density	1,930Kg/m^3 (Maximum dry density – MDD)
	Optimum moisture content	12%
Linear shrinkage	Linear shrinkage	10%
Permeability	Permeability	4.09 x 10^{-7} m/s
Unconfined compressive strength	Unconfined compressive strength	0.2MPa @ 95% MDD

Notes:
[1] Referring to the Atterburg Limits Chart in Figure 2.1, we can see that the ideal stabiliser for this soil is cement.
[2] A heavy compaction test was carried out to determine density and OMC:
The results are discussed in Section 6.4.7.

Water bearing test on finished tanks

RE2 was filled using a bowser. It was filled quickly using a motorised pump. The tank held water for about 8 hrs but damp patches appeared at the base of the tank. ‘Piping*’ caused loss of water which became critical after about 12hrs and there was a total loss of water after approximately 14hrs. As the wall became damper, 3 major cracks appeared in the tank wall. The possible reasons for the failure are discussed in Sections 6.4.7 and 6.4.8.

*Piping is a term used in the dam industry and is a mode of failure whereby water finds a path from one side of the dam wall to the other and the subsequent erosion of the wall causes failure.

Figure 7.10 The experimental rammed earth tank under construction at Kyera Farm, Mbarara, Uganda.

As a result of the failure of RE2, RE1 was relined and is awaiting slow filling by rain. RE1 has not yet be tested at full working water pressure.

7.6. Results of field and laboratory tests

Some observations regarding the laboratory tests:

- The results of the sieve analysis shows that the soil is suitable for RE construction.
- Referring to the Atterburg Limits Chart in Figure 2.2, we can see that the ideal stabiliser for this soil is cement.
- Compaction density (MDD) seems rather low – normally we would expect a MDD of at least 2000Kg/m^3.
- OMC seems rather high – this is normally in the range of 8 – 10%
- Permeability is high at 4.09 x 10^{-7}m/s. The norm for stabilised soil is 1 x 10^{-8}m/s.
- Unconfined compressive strength seems very low and this figure is not trusted.
- Linear shrinkage is also high.

The result of the water bearing test described in Section 7.4. was discouraging as far as the overall viability of RE tank technology is concerned. The failure highlighted a number of points:

- Soil tanks should have sufficient wet tensile strength to cope with total saturation in water. This has a strong impact on the design of such tanks and could result in excessive wall thickness.
- A tensile reinforcement should be included within the soil matrix to prevent catastrophic failure in the event of saturation.
- A good tank lining is critical. A poor leakage of the lining will cause rapid degradation of the wall.
- Where a waterproofing agent is used in a render lining it should be given adequate time to take effect. Follow the manufacturers instructions and where they are

lacking, fill the tank slowly, at no more than 200mm per day after 2 weeks of curing in a saturated environment.

7.7. Observations made regarding the RE tank construction technique and field tests

The construction technique developed in the laboratory was further refined in the field. The following observations were made:

- Soil preparation was initially very time consuming, until a groundnut sheller was acquired and modified to mill soil through a 4mm sieve (see Appendix IV). This reduced soil preparation time to about one tenth.
- RE construction is a time consuming process. The cost analysis in Section 6.5 shows how labour intensive the process can be.
- The shuttering used in the field had no radial arms and so the reaction discussed in Section 7.3 was dealt with by standing on the shuttering whilst ramming.
- The level of accuracy attained in the field was lower than in the laboratory. This was not a problem, however, as soil was cut away with a machete if the geometry was not perfect. This was more feasible in the field as the wall thickness of these tanks was higher.
- Some work was carried out to assess the feasibility of plastic liners for use with soil tanks. There were problems in a number of areas: finding good quality plastic sheet; finding plastic sheet of a suitable size; abrasion of liners when in use causing small puncture holes. The technique is not recommended for use at present.

Limitations of the field tests Time constraints were tight due the limited amount of time in-country. It was difficult to set up and execute proper tests during the limited time available, the construction process itself being very time consuming. The tests that were carried out were done so hurriedly and give only an indicative feel for the behaviour of the tank.

7.8. Conclusions, discussion and planned further work concerning RE tanks

Discussion The probable mode of failure of RE2 is outlined in this Section. It appears that water passed through the lining of the tank almost immediately the water was placed in the tank. It seems probable that the waterproofing agent had had insufficient time to act and that water was passing through the render under full water pressure. Alternatively, the lining was of poor quality and water passed through cracks in the lining. The water forced its way through the soil matrix under piping action until it emerged at the outer face of the wall, and the resultant erosion increased the ‘pipe’ area until the water could flow freely from the tank (see Figure 7.11).

The fact that cracks appeared in the tank wall mean that the wet strength of the soil was insufficient to withstand the forces exerted through normal working water pressure, which is not tolerable.

Figure 7.11 Failure of RE2 through 'piping' – this figure shows the leakage at the base of the tank and the crack running through the wall

Further work on RE Tanks A similar water pressure test will be carried out on RE1, as was carried out on RE2. This tank has been relined and will be filled with rain during the coming wet season (starting September 2000). Staff at Kyera Farm have been asked to observe the tank as it slowly fills.

The following is a list of further work that is recommended to clarify uncertainties regarding the technique:

- Performance tests on soil samples taken from field
- Further investigations into suitable levels of soil stabilisation
- Investigation of techniques for improving wet strength of stabilised soil
- Investigation of techniques for decreasing permeability of stabilised soil (e.g. inclusion of bitumen emulsion)
- Further field tests including destructive tank pressurisation tests
- Further work to develop suitable plastic or other flexible linings

8. Cost analysis

A cost analysis for an 11 cubic metre ferrocement tank and an 11 cubic metre rammed earth tank has been carried out

The bill of quantities for the ferrocement tank was taken from Gould and Nissen-Peterson, 1999. The rammed earth tank is an externally rendered tank fitted with a thin-shell ferrocement cover. It is also fitted with a plastic 'sock' lining as described later in this document. Hoop strength is augmented using barbed wire hoops spaced every 0.1m for the entire height of the tank. Cement content is 5% and moisture content of the soil is 8%. We have used material prices based on costs in Uganda as of August 1999. This allows us to make a realistic analysis using costs from a single location and an identical size of tank. We are therefore making a direct cost comparison. The cost comparison and relative benefits may change if the costing is repeated for a different location (with different prices). India, for example, has lower

cement prices, which would impact greatly on this comparison. One pound sterling is roughly equivalent to 2440 Ugandan shillings (UGX) as of January 2000. Transportation costs for materials (other than sand) are not included.

The costing figures are shown in the table in APPENDIX I and the table is self-explanatory. Some points to consider are:

- Cement is the major cost in the ferrocement tank. There is little means of reducing the cost without reducing wall thickness. Transportation of cement can be costly if the site is remote.
- The cost, including labour, of the thinner walled rammed earth tank is about 80% that of the ferrocement tank. Material costs are about 72%. This reflects the higher labour input required.
- If suitable soil is available on site then the material costs of the RET can be reduced significantly.
- The RET wall sits on a concrete ring rather than a concrete disc. The base of the tank is of compacted earth. This helps reduce costs as concrete raft bases consume significant quantities of material and are therefore expensive.
- The RET wall is stabilised. The wall would have sufficient strength without stabilisation and the cost could be reduced further. Stabilisation is desired however in case of wetting of the wall.
- If stabilisation and reinforcing is omitted, the cost of the (thinner-walled) RET drops to 697,000 UGX or £278.28, 58.5% that of the ferrocement tank cost (including labour).
- Tooling costs, shuttering and moulds in particular, tend to be higher for the ferrocement tank, although for both tanks the moulds / shuttering can be reused many times.

9. General conclusions, discussion and plans for further work

9.1. Discussion

A number of stabilised soil tanks have been constructed and tested, using two different soil construction techniques. Two tanks have failed under test and the failures have been analysed in the relevant sections of the report. Two further tanks are still under test. Some important lessons have been learned from the initial tests and these lessons will be used to guide further research. The main lessons learned are listed here:

- When designing stabilised soil tanks one should take into consideration wet tensile strength of the material. It is inappropriate to use the dry tensile strength as the design strength value unless it can be guaranteed that water will never reach the soil matrix.
- A composite tensile member is recommended to prevent sudden catastrophic failure of a tank.
- Tank linings should be fully impermeable to prevent water reaching the soil matrix.
- Plastic linings

9.2. Recommended further work

Stabilised soil block tanks

- Full laboratory analysis of the soil
- Performance tests to determine the soil / block characteristics
- Further full scale tank tests with some modifications to improve tank performance
- Investigate methods for improving tensile strength e.g. reinforcing with barbed wire

Rammed earth tanks - Laboratory work

- Manufacture of sealed cover and tank pressurisation equipment
- Pressure testing of the existing experimental tank
- Data logging to allow analysis of the stresses in the tank during pressurisation
- Performance tests to analyse the soils characteristics in use
- Experiments to determine the effects of cement content on stabilisation
- Experiments to determine the effect of cyclic loading on rammed earth tank walls (cracking, joint failure, etc.)
- Waterproof lining (cyclic loading with a variety of 'sharp' objects to test resistance to penetration, fixing methods, liner penetration for off-take, etc)
- Wet strength tests of tanks

Rammed Earth Tanks - Field work

- Performance tests on soil samples taken from field
- Further investigations into suitable levels of soil stabilisation
- Investigation of techniques for improving wet strength of stabilised soil
- Investigation of techniques for decreasing permeability of stabilised soil (e.g. inclusion of bitumen emulsion)
- Further field tests including destructive tank pressurisation tests
- Further work to develop suitable plastic or other flexible linings

Other work

- Render linings for tanks – permeability tests and effects of waterproofing agent on render (both in early stages and longer term)
- Methods for reducing permeability of compacted soils (e.g. treatment with bitumen emulsion)
- Further experiments on the relationship between wet and dry strength in tension
- Tank linings from plastics
- Termite attack on soil tanks
- Sliding joint at base of tank

APPENDIX II - REPORT ON WATER TANKS FROM STABILISED SOIL BLOCKS

(by Engineer Dr. M. K. Musaazi PhD DIC, August 2000)

Machinery

Manual Block Press (by ApproTec Kenya): Specially modified by authorized manufacture (Makiga Engineering Services, Kenya) to make curved interlocking blocks. There are two Block Presses designed so that 13 blocks interlock to make a 1.0m internal diameter circle or 17 blocks make a 1.5m internal diameter circle.

Material

Murrum (red) soil or volcanic soil and Ordinary Portland Cement (OPC)

Material Preparation

Sieve soil with a 5mm wire mesh. Mix while dry with OPC in the ratio.

Cement : Soil = 1: 19

i.e. 50kg(l bag) of OPC makes 110 SSB blocks each of about 9kg. A little water is added to make the mixer just damp.

Block Making

Prepared material compressed by 40% to make one block at a time.
Two men make 330 blocks/day.

Curing and Drying of Blocks

Blocks are cured under a black Polythene sheeting for five days if made from murrum and for 2 days if from volcanic soil. Dried for 5 days under direct sunshine, after curing, before used to make tanks.

Tank Building

A 150 mm concrete base is made and blocks laid the following day. Blocks interlock to form a circle desired internal diameter.

Experience has shown that the internal diameter can be increased from design by as much as 0.5m without any noticeable distortion of the circle.

The blocks are laid using a 1:4 cement to sand ratio. One bag (50kg) of OPC lays about 200 blocks. The inside of the tank is plastered with fine sand, OPC and water proof cement (I kg added to 50kg of OPC).

Block Size:

Length = 280 mm
Width = 140 mm
Height = 110mm

Hence the tank wall is 140 mm thick plus 10 mm of plaster.

Tank Sizes

The size of course depends on the internal diameter and height. The tanks that have NOT failed number five as tabled below:

TANK NO.	DIMENSIONS	CAPACITY (Litres)	WHEN MADE MONTH, 2000	REMARKS
1	Int diam – 1.0m Height - 5.2m Block layers – 13 Total blocks – 507	5,800	March	Full up to 3.5m as of 1st August 2000
2	Int diam – 1.24m Height - 2.12m Block layers – 15 Total blocks – 240	2,500	March	Full to capacity as of 1st August 2000
3	Int diam – 1.20m Height - 2.12m Block layers – 14 Total blocks – 210	2,400	April	Full to capacity as of 1st August 2000
4	Int diam – 1.20m Height - 2.12m Block layers – 14 Total blocks – 210	2,400	April	Full to capacity as of 1st August 2000
5	Int diam – 1.20m Height - 2.12m Block layers – 14 Total blocks – 210	2,400	May	Full to capacity as of 1st August 2000

One tank that ruptured when trying to fill it with water had the following dimensions:

Int. Dia = 1.67 m
Height = 3.80 m
Blocks/layer = 19
No. of layers = 28
Capacity = 8.324 litres

Tank ruptured when about 2.5m full.

Possible causes of tank failure:

(i) Diameter too large, hence insufficient hoop strength
(ii) Filled too quickly with a tanker – this does not give the waterproofing agent time to work properly

(iii) Blocks from volcanic soil seem not to have been stabilised – broken blocks disintegrated completely when soaked in water. This could be due to poor workmanship, although the building team are known and trusted.

(Figure AII.1 – Tank built for experimental tests in Uganda)

(Figure AII.2 – failure of the SSB tank was catastrophic – the debris remaining after failure is shown here)

APPENDIX IV – Rammed Earth Tank Construction Guidelines

Including Shuttering and Rammer Drawings

Milestone A4

Completion of three partially below ground tanks, 2 rammed earth tanks, eight cement jars and two stabilised soil block tanks.

(Originally titled 'Completion of 3 sets of 4 tanks and associated instrumentation')*

Development Technology Unit (DTU)

University of Warwick

April 2000

Milestone A4 - Table of Contents

1. Introduction.....2
2. Construction of three partially below ground tanks.....2
3. Construction of two rammed earth tanks.....6
4. Construction of eight cement jars for water quality experiments.....9
5. Construction of two stabilised soil block tanks in Kampala, Uganda 10

Funded by the European Commission

*Please see the introductory section for an explanation of the change in the title of this report.

1. Introduction

As mentioned in the Milestone A3 Report, early in the programme, after the initial desk study had identified the areas where further research is required, it was decided to broaden the original scope of the water storage (technology) component of the programme to include above ground, free-standing water storage tanks as well as underground tanks. The focus of the work was, initially, broadened to look at tank covers and reinforced brick tanks. We have since moved forward with more radical cost reduction ideas and have been experimenting with two very low cost water storage ideas: the partially below ground tank and the rammed earth tank. We also carried out some water quality experiments in Uganda to test the acceptance of water from cement lined storage vessels. For these experiments we constructed eight 400litre cement jars. Finally, through our connections with Uganda we were asked to carry out some collaborative research with Mr Moses Musaazi of Makerere University into the use of cement stabilised soil blocks for the construction of above-ground water storage tanks.

The title of this Milestone has therefore been altered to reflect the practical research work that has actually been carried out under the programme.

A brief overview of the work that has been completed for this Milestone is given in this report. A fuller report of the work that has been carried out, including the experiments carried out and results obtained for each of the pieces of work mentioned above, will be presented in Milestone A5 (Report A3 '*Performance of Tanks for DRWH'*). This report will be submitted in the near future.

2. Construction of three partially below ground tanks

As reported in Milestone A3, work was started on the design of the Partially Below Ground (PBG) tank in Uganda last year. The work has still, to date, been primarily field based and three tanks have been built until now, in the vicinity of Kyenjojo, Kabarole District in Western Uganda. The tanks have been built by our partner organisation, ARUCED. ARUCED has also received orders for a number of these tanks to be built privately and to date eight tanks in all have been built.

The aim of the design of the PBG is to minimise the amount of material used by partially submerging the tank below ground – the major benefit of sub-surface tanks. The fact that approximately 1metre of the tank protrudes above the ground helps overcome some of the drawbacks normally associated with below ground tanks (see Table 1 below). The ground conditions in this part of SW Uganda are ideally suited to this kind of tank, being lateritic and highly stable.

	Above ground tank	Below ground tank
Pros	• Above ground structure allows for easy inspection for cracks or leakage • Many existing designs to choose from • Can be easily purchased 'off-the-shelf' in most market centres • Can be manufactured from a wide variety of materials • Easy to construct for traditional materials • Water extraction can be by gravity in many cases • Can be raised above ground level to increase water pressure	• Generally cheaper due to lower material requirements • More difficult to empty by leaving tap on • Require little or no space above ground • Unobtrusive • Surrounding ground gives support allowing lower wall thickness and thus lower costs
Cons	• Require space • Generally more expensive • More easily damaged • Prone to attack from weather • Failure can be dangerous	• Water extraction is more problematic – often requiring a pump • Leaks or failures are more difficult to detect • Contamination of the tank from groundwater is more common • Tree roots can damage the structure • There is danger to children and small animals if tank is left uncovered • Flotation of the cistern may occur if groundwater level is high and cistern is empty heavy vehicles driving over a cistern can cause damage

Table 1. Pros and Cons of Tanks and Cisterns

The design also tries to minimise the amount of cement used by employing a plastic liner to form the water proof lining for the tank. Until now the plastic liner has not, however, been fitted and the water proofing has been achieved by means of cement render. Further work in Uganda in the coming months will include the manufacture of plastic liners and these will be fitted to subsequent tanks.

Figure 1 – Schematic drawing of the Partially Below Ground Tank

A costing exercise has been carried out to estimate the benefits of using the PBG tank against the traditional ferrocement tank (assumed to be amongst the cheapest options) and the rammed earth tank (described below). A brief summary is given Table 2.

	Ferro-cement tank	***Rammed earth tank***	***Partially below ground tank***
Material	394	179	107
Labour	81	98	90
Total cost	475	277	197

Table 2 - Comparison of costs between a ferrocement, rammed earth and PBG tank – all 11 cubic metres

Each of the PBG tanks was fitted with a thin shell ferrocement cover, described in a previous report and developed under this programme.

Figure 2 – A thin shell ferrocement cover near completion and ready for fitting to a PBG tank

Figure 3 - A completed PBG tank showing inlet pipe and handpump for extracting water

Initial leakage tests were carried out on a number of tanks using a device developed at Warwick (see Figure 4). These tests are continuing at present and will be reported later.

Figure 4 – Leakage test apparatus being tested in the field on a PBG tank

3. Construction of two rammed earth tanks

The direction of the experimental work at the University has shifted from reinforced brick tanks (reported in Milestone A3) to a more radical design of tank – the rammed earth tank. The aim is to adopt a low-cost technique commonly used for house building in areas of the world such as North Africa, North and South America and the Middle East. The technique uses a mixture of sand and clay, sometimes with a small amount of stabiliser such as cement, which is rammed, either manually or pneumatically, between wooden shutters. To use rammed earth as the structural material in a water storage vessel a waterproof liner is required. This can be provided by employing one of a number of possible options, such as cement render or a plastic sheet liner (as mentioned earlier, this latter is being developed for this application at the University). It is a technique that is relatively simple in essence and requires little in the way of imported material.

Figure 5 – A section of wall rammed between the wooden shuttering shown after removal of the shuttering

So far, the work that has been done on rammed earth tanks has been experimental, and mainly focused on adapting the basic technique (generally used for construction of straight walls in the building sector), to the construction of circular walls for water storage tanks. A 0.7m inner radius quadrant shuttering (see Figure 5) was manufactured and a number of test sections were rammed using a locally excavated soil (local to the University). The soil had to be modified somewhat to make it suitable in terms of cohesion. Wall thickness was increased gradually from a starting minimum of 60mm. We eventually opted for a 100mm wall thickness although even this is unsuitable for manufacture in the field. It is ideal, however, for testing purposes.

A tank, of radius 0.7m and depth 0.7m, has been constructed in a test pit at the University, and fitted with a plastic liner. The tank has been fitted with steel straps to give added hoop strength, but these will be removed after initial tests. The straps will be fitted with strain gauges and will be linked to computer data logging equipment. Measurements of strain, water depth, and temperature will be taken during tests. It is hoped that full-scale testing will take place within the coming month (May 2000). The aim is to seal the top of the tank with a large wooden disc, which will be pierced with a header pipe. The water pressure head will be gradually increased to a maximum of 5m while logging the variation in strain and water depth. The tank has been designed to fail at about 4m, so the test should be destructive, giving valuable information on the strength of rammed earth as a possible alternative to conventional building materials.

Figure 6 – Bird's eye view of the rammed earth tank under construction in the test pit at the University

Figure 7 – Revised shuttering arrangement shown during construction of the experimental tank

4. Construction of eight cement jars for water quality experiments.

There has been much discussion about the acceptability of water that is stored in vessels lined with cement mortar. Many users complain about the taste of the water, especially in the early days when the cement is still leaching calcium. An experiment was set up in Uganda, and carried out by the DTU's partner organisation, ARUCED. Eight small jars of 400 litres each were build and cured using different methods. The aim these experiments was to try to quantify the acceptability of water from cement lined vessels that were cured in a number of different ways. The experiment was designed to determine the efficacy of 8 different curing regimes in the search to find a regime that would minimise the taste problem. The experiment was also used to look at some technical aspects of small cement jars, as well as the user aspects of small rainwater jars and their benefits to users.

The outcome of the taste experiment has been unsatisfactory. There were a number of problems with the experiment, many of which were outside the control of the people involved, but some due to poor experimental procedure. They included:

- Key staff leaving the organisation during the experiments
- Failure of equipment that had been taken to Uganda from the UK
- Curing water being taken from an unknown source
- Poor siting of tanks which meant that sampling was difficult on a daily basis

Figure 9 - 400 litre water storage jars being constructed as part of the water quality testing experiments in Uganda

A full report on the taste experiments will be presented later. The user studies are still underway. On a technical level, a number of findings have been made:

- Significant training is required to teach local masons the art of jar construction using this technique (the technique was taken directly from a classic ferrocement construction manual by S. B . Watt titled 'Ferrocement Water Tanks' [It Publications 1978]).
- Often the jars failed because the walls were of insufficient thickness – some method is needed of

5. Construction of two stabilised soil block tanks in Kampala, Uganda

In March 2000, two experimental cylindrical water tanks were built at Kawempwe, Kampala in collaboration with Dr Muses Musaazi, a lecturer at Makerere University. Both were built above ground of curved stabilised-soil blocks with end interlocking, 280mm x 140mm x 110mm high, made with an Approtec (Kenyan) manual block press. The soil used was a red somewhat pozzolanic local soil previously known to make strong blocks. The tanks were built on concrete plinths, lined with 'waterproofed' mortar (3 parts sand, 1 part cement and .02 parts 'Leak Seal' waterproofing compound). There was no metal reinforcing.

Figure 10 – Showing one of the stabilised soil block tanks under construction

Tank 1 is 2050mm high, has internal diameter 1300mm, wall thickness 140mm (+ 15mm render) and used 15 x 15 = 225 blocks incorporating 6% cement (100 blocks per 50kg bag). It has been filled with water and therefore has withstood a maximum head of 2.05m at the wall bottom. Volume = 2720 litres, max hoop stress = 0.19 MPa

Tank 2 is 1880mm high, has internal diameter 1000mm and the same wall thickness, but used 12 x 14 = 168 blocks with only 3% cement (180 blocks per 50 kg bag). It has been filled with water and therefore withstood a head of 1.88m at the wall bottom. Construction is continuing to extend its height up to 4m, testing its ability to resist

pressure forces at both 3m and 4m head. Volume = 1476 litres, maximum hoop stress (so far) = 0.13 MPa.

Materials use included 1 packet (50kg costing $\$_{US}11$) of cement for the render, 1 packet for a conical (reinforced) lid, 1 packet for mortar between the blocks and ½ packet in the foundation. Thus only $^{1}/_{5}$ to ¼ of the cement is in the blocks themselves. Experiments to achieve curved blocks with *vertical* interlocking, if successful, will significantly reduce the quantity of mortar needed for block-laying. The lid may well be made more cheaply, as that employed was designed to carry certain testing devices.

Figure 11 – Showing the interlocking blocks used for the tanks

Root cause analysis

From Wikipedia, the free encyclopedia

Root cause analysis (**RCA**) is a method of problem solving used for identifying the root causes of faults or problems.[1] A factor is considered a root cause if removal thereof from the problem-fault-sequence prevents the final undesirable event from recurring; whereas a causal factor is one that affects an event's outcome, but is not a root cause. Though removing a causal factor can benefit an outcome, it does not prevent its recurrence with certainty.

For example, imagine a fictional segment of students who received poor testing scores. After initial investigation, it was verified that students taking tests in the final period of the school day got lower scores. Further investigation revealed that late in the day, the students lacked ability to focus. Even further investigation revealed that the reason for the lack of focus was hunger. So, the root cause of the poor testing scores was hunger, remedied by moving the testing time to soon after lunch.

As another example, imagine an investigation into a machine that stopped because it overloaded and the fuse blew.[2] Investigation shows that the machine overloaded because it had a bearing that wasn't being sufficiently lubricated. The investigation proceeds further and finds that the automatic lubrication mechanism had a pump which was not pumping sufficiently, hence the lack of lubrication. Investigation of the pump shows that it has a worn shaft. Investigation of why the shaft was worn discovers that there isn't an adequate mechanism to prevent metal scrap getting into the pump. This enabled scrap to get into the pump, and damage it. The root cause of the problem is therefore that metal scrap can contaminate the lubrication system. Fixing this problem ought to prevent the whole sequence of events recurring. Compare this with an investigation that does not find the root cause: replacing the fuse, the bearing, or the lubrication pump will probably allow the machine to go back into operation for a while. But there is a risk that the problem will simply recur, until the root cause is dealt with.

Following the introduction of Kepner–Tregoe analysis—which had limitations in the highly complex arena of rocket design, development and launch—RCA arose in the 1950s as a formal study by the National Aeronautics and Space Administration (NASA) in the United States. New methods of problem analysis developed by NASA included a high level assessment practice called MORT (Management Oversight Risk Tree).[3][4][5] MORT differed from RCA by assigning causes to common classes of cause shortcomings that could be summarized into a short list. These included work practice, procedures, management, fatigue, time pressure, along with several others. For example: if an aircraft accident occurred as a result of adverse weather conditions augmented by pressure to leave on time; failure to observe weather precautions could indicate a management or training problem; and lack of appropriate weather concern might indict work practices. Because several measures (methods) may effectively address the root causes of a problem, RCA is an iterative process and a tool of continuous improvement.

RCA is applied to methodically identify and correct the root causes of events, rather than to simply address the symptomatic result. Focusing correction on root causes has the goal of entirely preventing problem recurrence. Conversely, RCFA (Root Cause Failure Analysis) recognizes that complete prevention of recurrence by one corrective action is not always possible.

RCA is typically used as a reactive method of identifying event(s) causes, revealing problems and solving them. Analysis is done *after* an event has occurred. Insights in RCA make it potentially useful as a preemptive method. In that event, RCA can be used to *forecast* or predict probable events even *before* they occur. While one follows the other, RCA is a completely separate process to incident management.

Rather than one sharply defined methodology, RCA comprises many different tools, processes, and philosophies. However, several very-broadly defined approaches or "schools" can be identified by their basic approach or field of origin: safety-based, production-based, assembly-based, process-based, failure-based, and systems-based.

- Safety-based RCA arose from the fields of accident analysis and occupational safety and health.
- Production-based RCA has roots in the field of quality control for industrial manufacturing.
- Process-based RCA, a follow-on to production-based RCA, broadens the scope of RCA to include business processes.
- Failure-based RCA originates in the practice of failure analysis as employed in engineering and maintenance.
- Systems-based RCA has emerged as an amalgam of the preceding schools, incorporating elements from other fields such as change management, risk management and systems analysis.

Despite the different approaches among the various schools of root cause analysis, all share some common principles. Several general processes for performing RCA can also be defined.

Contents

- 1 General principles
- 2 General process for performing and documenting an RCA-based corrective action

General principles

1. The primary aim of root cause analysis is: to identify the factors that resulted in the nature, the magnitude, the location, and the timing of the harmful outcomes (consequences) of one or more past events; to determine what behaviors, actions, inactions, or conditions need to be changed; to prevent recurrence of similar harmful outcomes; and to identify lessons that may promote the achievement of better consequences. ("Success" is defined as the near-certain prevention of recurrence.)
2. To be effective, root cause analysis must be performed systematically, usually as part of an investigation, with conclusions and root causes that are identified backed up by documented evidence. A team effort is typically required.
3. There may be more than one root cause for an event or a problem, therefore the difficult part is demonstrating the persistence and sustaining the effort required to determine them.
4. The purpose of identifying all solutions to a problem is to prevent recurrence at lowest cost in the simplest way. If there are alternatives that are equally effective, then the simplest or lowest cost approach is preferred.
5. The root causes identified will depend on the way in which the problem or event is defined. Effective problem statements and event descriptions (as failures, for example) are helpful and usually required to ensure the execution of appropriate analyses.
6. One logical way to trace down root causes is by utilizing hierarchical clustering data-mining solutions (such as graph-theory-based data mining). A root cause is defined in that context as "the conditions that enable one or more causes". Root causes can be deductively sorted out from upper groups of which the

groups include a specific cause.
7. To be effective, the analysis should establish a sequence of events or timeline for understanding the relationships between contributory (causal) factors, root cause(s) and the defined problem or event to be prevented.
8. Root cause analysis can help transform a reactive culture (one that reacts to problems) into a forward-looking culture (one that solves problems before they occur or escalate). More importantly, RCA reduces the frequency of problems occurring over time within the environment where the process is used.
9. Root cause analysis as a force for change is a threat to many cultures and environments. Threats to cultures are often met with resistance. Other forms of management support may be required to achieve effectiveness and success with root cause analysis. For example, a "non-punitive" policy toward problem identifiers may be required.

General process for performing and documenting an RCA-based corrective action

RCA (in steps 3, 4 and 5) forms the most critical part of successful corrective action, directing the corrective action at the true root cause of the problem. Knowing the root cause is secondary to the goal of prevention, as it is not possible to determine an absolutely effective corrective action for the defined problem without knowing the root cause.

1. Define the problem or describe the event to prevent in the future. Include the qualitative and quantitative attributes (properties) of the undesirable outcomes. Usually this includes specifying the natures, the magnitudes, the locations, and the timing of events. In some cases, "lowering the risks of reoccurrences" may be a reasonable target. For example, "lowering the risks" of future automobile accidents is certainly a more economically attainable goal than "preventing all" future automobile accidents.
2. Gather data and evidence, classifying it along a timeline of events to the final failure or crisis. For every behavior, condition, action and inaction, specify in the "timeline" what should have been done when it differs from what was done.
3. In data mining Hierarchical Clustering models, use the clustering groups instead of classifying: (a) peak the groups that exhibit the specific cause; (b) find their upper-groups; (c) find group characteristics that are consistent; (d) check with experts and validate.
4. Ask "why" and identify the causes associated with each sequential step towards the defined problem or event. "Why" is taken to mean "What were the factors that directly resulted in the effect?"
5. Classify causes into two categories: causal factors that relate to an event in the sequence; and root causes that interrupted that step of the sequence chain when eliminated.
6. Identify all other harmful factors that have equal or better claim to be called "root causes." If there are multiple root causes, which is often the case, reveal those clearly for later optimum selection.
7. Identify corrective action(s) that will, with certainty, prevent recurrence of each harmful effect and related outcomes or factors. Check that each corrective action would, if pre-implemented before the event, have reduced or prevented specific harmful effects.
8. Identify solutions that, when effective and with consensus agreement of the group: prevent recurrence with reasonable certainty; are within the institution's control; meet its goals and objectives; and do not cause or introduce other new, unforeseen problems.
9. Implement the recommended root cause correction(s).
10. Ensure effectiveness by observing the implemented solutions in operation.
11. Identify other possibly useful methodologies for problem solving and problem avoidance.
12. Identify and address the other instances of each harmful outcome and harmful factor.

Root cause

From Wikipedia, the free encyclopedia

A **root cause** is an initiating cause of either a condition or a causal chain that leads to an outcome or effect of interest. Commonly, **root cause** is used to describe the depth in the causal chain where an intervention could reasonably be implemented to improve performance or prevent an undesirable outcome.

In plain English a "root cause" is a "cause" (harmful factor) that is "root" (deep, basic, fundamental, underlying, initial or the like).

The term **root cause** has been used in professional journals as early as 1905.[1]

Paradies (2005) has defined a root cause as follows: "The most basic cause (or causes) that can reasonably be identified that management has control to fix and, when fixed, will prevent (or significantly reduce the likelihood of) the problem's recurrence." [2]

Fantin (2014) describes the root cause as the result of the drill down analysis required to discover which is the process that is failing, defining it as "MIN Process" (meaning a process that is Missing, Incomplete or Not followed)[3]

About Root-Cause discovery, see Root cause analysis.

Root cellar

From Wikipedia, the free encyclopedia

A **root cellar** is a structure built underground or partially underground and used to store vegetables, fruits, and nuts or other foods.

Interior of a large Wyoming root cellar with crops

Contents

- 1 Function
- 2 Construction
- 3 See also
- 4 References

A pair of modern potato cellars in southeastern Idaho

Function

Root cellars are for keeping food supplies at a low temperature and steady humidity. They keep food from freezing during the winter and keep food cool during the summer months to prevent spoilage. Typically, a variety of vegetables are placed in the root cellar in the autumn, after harvesting. A secondary use for the root cellar is as a place in which to store wine or home-made alcoholic beverages.

Two traditional sod-covered potato cellars in southeastern Idaho

Vegetables stored in the root cellar primarily consist of potatoes, turnips, and carrots. Other food supplies placed in the root cellar over the winter months include beets, onions, jarred preserves and jams, salt meat, salt turbot, salt herring, winter squash, and cabbage.[1] A potato cellar is sometimes called a potato barn or potato house.

Separate cellars are occasionally used for storing fruits, such as apples. Water, bread, butter, milk, and cream are sometimes stored in the root cellar also. In addition, items such as salad greens, fresh meat, and jam pies are kept in the root cellar early in the day to keep cool until they are needed for supper.[2]

Construction

Common construction methods are:

1. Digging down into the ground and erecting a shed or house over the cellar (access is via a trap door in the shed).
2. Digging into the side of a hill (easier to excavate and facilitates water drainage).

3. Building a structure at ground level and piling rocks, earth, and/or sod around and over it. This may be easier to build on rocky terrain where excavation is difficult.

Most root cellars were built using stone, wood, mortar (cement), and sod. Newer ones may be made of concrete with sod on top.[2]

PREFACE

UNIFEM AND THE FOOD CYCLE TECHNOLOGY PROJET (WAFT)

The United Nations Development Fund for Women (UNIFEM) was established in 1976, and is an autonomous body associated, since 1985, with the United Nations Development Programme. UNIFEM seeks to free women from under-productive tasks and augment the productivity of their work as a means of accelerating the development process. It does this through funding specific economic projects which yield direct benefits and through actions directed to ensure that all development policies, plans, programmes and projects take account of the needs of women producers.

In recognition of women's special roles in the production, processing, storage, preparation and marketing of food, UNIFEM initiated in 1985 a Food Cycle Technologies project with the aim of promoting the widespread diffusion of tested technologies to increase the productivity of women's labour in this sector. While global in scope, this five-year project is initially being implemented in Africa in view of current concerns over food security in many countries of the Region.
The eventual aim of the project is to increase indigenous capacity to respond to the technology needs of women producers and to inform and influence the decision makers who can create the correct policy environment for this to happen. This will be achieved by providing appropriate technical assistance relating to the process of technology development and diffusion.

This source book is one of a series being compiled as part of the preparatory phase of the Food Technology project. UNIFEM hopes that the widespread distribution of these sourcebooks will increase awareness of the range of technological options and sources of expertise, as well as indicating the complex nature of designing and successfully implementing technology projects and diffusion programmes.

Titles in this series include: Oil Extraction, Fruit and Vegetable Processing, Cereal Processing, Root Crop Processing, Fish Processing, Packaging, Drying and Storage. Source books will also be available in French and Portuguese.

ACKNOWLEDGEMENTS

This initial series of food cycle technology source books has been prepared at the Intermediate Technology Development Group (ITDG) in the United Kingdom within the context of UNIFEM's Women and Food Cycle Technologies (WAFT) specialization. During the preparation process the project staff have contacted numerous project directors, rural development agencies, technology centers, women's organizations, equipment manufacturers and researchers in all parts of the world.

UNIFEM and ITDG wish to thank the several hundred agencies and individuals who have contributed to the preparation of the source books. Not all can be mentioned by name, but special thanks are owed for their major contributions to the International Labour Organization (ILO), the Food and Agriculture Organization of the United Nations (FAO), the United Nations Children's Fund (UNICEF), the Economic Commission for Africa (ECA), the German Appropriate Technology Exchange (GATE/GTZ) in Eschborn, the Groupe de Recherche et d'Echanges Technologiques (GRET) in Paris, the Royal Tropical Institute (KIT) in Amsterdam, the International Development Research Centre (IDRC) in Ottawa, the Tropical Development Research Institute (TDRI) in London, Appropriate Technologies International (ATI) in Washington, the Institute of Development Studies, Sussex University (IDS), and the Save the Children Fund.

The preparation of the source books has been funded by UNIFEM with a cost sharing contribution from the Government of The Netherlands.

UNIFEM is particularly grateful to the Government of Italy for providing the funds for translation and printing of the source books and to the Italian Association for Women in Development (AIDOS) for implementing this phase of the project.

FURTHER READING 67

CONTACTS 72

This book will cover the small scale processing of tropical root crops in developing countries with the intention of providing UNIFEM consultants with technical understanding of traditional and improved technologies for use in these countries.

An illustration of the wider context into which such projects are found (in terms of socio-economic issues) is also given. This will enable the consultants to see any merits and/or problems of introducing technologies to different groups in various developing countries. In developing countries the family meals are usually prepared by women who are therefore involved in the various stages of processing the raw material for consumption. Root crops are a staple and hence are often the main part of the meal, especially where cereals are unavailable. Village scale processing of root crops is therefore an important part of womens' daily work. A substantial effort has been made to upgrade local processes but many communities still only have access to traditional methods which although appropriate are laborious.

Large scale production of starches, glucose syrups, animal feeds, gari etc from root crops is a commercial venture involving substantial capital investment. For direct human consumption, the processing of root crops is mainly at small scale, often at household level.

It would be impossible to cover all the root crops and processing techniques in a document of this size, so the more common methods of processing the more important root crops; cassava, yam, sweet potato, potato and edible aroids are discussed.

Emphasis is placed on cassava throughout this manual for several reasons. Even though the total world production for sweet potato may perhaps be greater, cassava's prime importance as a food in Africa, and the fact that it often requires special treatment to make it fit for human consumption, means that there are a greater variety of processing methods Finally small-scale cassava processing in developing countries has been researched and developed to a greater degree than any other root crop. This document is divided into several sections covering basic food science principles; traditional and improved small scale processing methods and equipment relevant to rural women: case studies illustrating the merits and problems of introducing improved technologies into a particular existing socio-economic framework; a list of summarising questions placing processing in the wider context of village situations, and a list of institutions to contact for information. It is important to realise that although a technology may be improved and tested technically in a research laboratory, workshop or field situation outside any community, it may prove to be inappropriate for the intended social setting. Although it is realised that one can only predict an outcome of introducing a technology trying it, it should be born in mind that assumptions can be made more accurately if consideration is given to the reality - that is, that rural women need recognition and access to relevant institutions, infrastructural support, extension workers and formal lines of credit.

Importance of root crops

The most important root crops in terms of tonnage production in developing countries are cassava, potato and sweet potato. There seems to be some disagreement over which is the most important, some sources favouring sweet potato (table 1), others cassava, but this is a

point of academic interest. While other major root crops such as yams and cocoyams are important foods in certain areas, their levels of production are considerably less.

It is estimated that 65% of cassava produced is for direct food use, the remainder being used in animal feed (30%) or processed into industrial products (5%). Reliable data on the ratios of other major root crops used for food and industrial uses are not readily available. Root crops are a cheap, available and essential energy source for many poor people who face problems of food availability. Although they contain little protein or fat, some, particularly potato and yam, are a source of vital vitamins (A and C).

Over half of the world's total cassava production is in Africa (table 2) and it has been estimated that 37% of the energy in the diet in tropical Africa comes from cassava. In the Americas and Asia the contribution is estimated to be only 12% and 7% respectively. Tropical rootcrops are mainly consumed and, where necessary processed at the village and household level. The relative importance of individual root crops varies both by region and country. Yams are a major food crop in West Africa, the Caribbean, the South Pacific Islands, Southeast Asia, India and parts of Brazil. Cassava is particularly important in South America, West, East, Central and South Africa, and Oceania. Taro plays an important cultural role in the diet of the people of the Pacific Islands, as does sweet potato in part of West Africa, Oceania and the West Indies. Potato, requiring a more temperate climate, is more important in highland areas of the tropics such as the Andean regions of Peru and Bolivia. The main advantages of root crops as a staple compared to cereals is that they are a cheaper source of energy, can be cultivated easily and provide more dietary energy per hectare at a lower cost to the farmer (principally because of reduced labour inputs). They generally require a comparatively low level of husbandry, especially cassava which can grow in very dry and nutrient-deficient soils, albeit with lower yields.

Some root crops have a production cycle which is continuous or semi-continuous, in contrast to cereal production, where harvesting is highly seasonal. Taro and cassava, for example, are grown in the tropics all year round. This can avoid storage problems and can provide increased food security for the poor, especially during periods of food shortage. The continuous cropping of root crops to act as a reserve food buffer allows many poor people to survive better the problems of seasonality and shortages of other food items. It should be noted, however, that the practice of only partially harvesting certain root crops and relying on their natural underground storage can create a problem of land availability for subsistence farmers.

The pre-harvest period of, for example, cereals is often the most difficult time for poor people. Not only can it be a 'hungry' period, but food prices are generally higher, food intake is at its lowest and labour requirements on the farm are rising in anticipation of harvest. The role of root crops at such times is thus of prime importance.

Women's role in processing

The majority of the labour required for the processing of all rootcrops is provided by women. It must be remembered, however, that the simple provision of labour does not ensure that women derive the benefits from a particular process. That depends much more on who controls the process — who makes the decisions on time allocation and the distribution of benefits gained. This control

Table 1

Value of production of ten principal food crops in all developing countries

	Number of producing countries	Production (million t)	Producer price ($t)	Value (billion $)
Rice	97	383	170	65

can sometimes lie with the grower of the crop rather than the processors or those who market the final product.

In some countries production and processing of a root crop is under women's control (eg cassava in West Africa), while in other regions it is a male prestige crop and taboo for women to cultivate it (as for example, with certain yams in Nigeria and a specific variety of swamp taro in the Pacific Islands).

It is important to take these considerations of control into account in any project. Let us imagine, for example, a situation where the man grows a crop on land he controls, while women process the produce of that land. If the man invests in a labour-saving process so that he can re-deploy his wife in the fields, saving him time, who has really benefitted? The community as a whole, yes, if the men can use their freed-up time productively; but the women have not benefitted at all, at least not directly.

In the case where the land, labour and material inputs are sufficiently under the woman's control, labour-saving technological improvements may have more direct impact on her own and her family's livelihood. It has been seen that even when women farmers control these inputs, they can suffer displacement with the introduction of mechanisation. For example, in parts of West Africa the introduction of motorized cassava graters has greatly improved the productivity of gari processing, making this an attractive economic activity to both men and women. It has been known to happen that cassava, once a 'women's crop', has been taken over by male members within a household, with the females having to look for alternative income opportunities once the production became mechanized.

It is vital that the women processors themselves are included in project design and implementation. Women producers are always trying to maximize their limited resources. It is vital to understand how they value these resources and the trade-offs they are willing to make in their distribution. Experience has shown that some technologies have not been accepted because they have not taken into account the perceived needs and priorities of the user.

Project design, therefore, should look beyond the immediate confines of the 'project'. The processing activity should be seen as part of a number of systems: firstly, a food production system of growing, processing and marketing; secondly an economic system of production and exchange, and thirdly, a social system of interactions between members of the same family, between families, sexes and clans, in the same community and between communities. Only then can a reasonable assessment of the likely distribution of benefits of introducing an improved technology be made.

SECTION 1

Pre-Processing and Processing Considerations

It is important to have a basic understanding of the physiology of any crop in order to be able to predict its post-harvest behaviour. This, together with a knowledge of certain essential food science principles and the chemical composition of the crop will put the consultant in a far better position to study and adapt a given processing system.

In this book, it will only be necessary to describe the general composition of root crops together with basic food science principles relevent to their processing. Socio-economic aspects of tropical root crops will also be discussed.

Raw Materials

Root crops, as the name implies, are plants that develop starchy roots, tubers, stems, bulbs or corms that act as a food store for the plant. Chemically, they are mainly composed of water and starch with minor amounts of protein, fibre, minerals, vitamins and, very importantly in some cases, toxic components.

The term 'root crops' can be somewhat misleading and, in this publication will cover commodities such as cassava, yams, potatoes, sweet potatoes and certain aroids all of which are staple food crops of high starch content. Aroids, such as taro, and tannia (known collectively as cocoyams in Africa), in which the starch is deposited in swollen stems are included for convenience with root crops. Bananas, plantains and other staple starchy fruits, while processed in ways very similar to root crops are not covered in this publication but rather in the relevant fruit and vegetable volume.

After the plant has finished growing and the foliage dies away, the 'food store' of many root crops survives by going into dormancy, the duration of which depends on both the crop type and variety. Cassava is the exception having no natural dormancy period.

The post-harvest storage life of a root crop thus depends on the type of crop as well, of course, as the conditions of storage. The end of post-harvest storage is signalled by sprouting and the removal of the sprouts can, in many cases, increase the storage period. This is particularly true of yams.

In addition to the main chemical components, such as starch, root crops contain important minor components. One of these is an enzyme called polyphenyloxidase, which causes the well-known effect of darkening of fresh cut surfaces on exposure to air. This effect, which can be controlled by the use of chemicals, or blanching in hot water or steam, needs to be taken into consideration in certain processing systems. Also, as previously mentioned, several root crops contain toxic substances, the most important being a cyanide-containing glycoside in cassava, and solanins in some varieties of potato. The presence of such toxic factors demands special processing procedures to make the product safe for human consumption. The cyanogenic glycoside complex of cassava can produce extremely toxic hydrogen cyanide through the action of natural enzymes in

the root. Levels of hydrogen cyanide range from 10 to over 450mg/kg of fresh root depending upon variety. In many countries consumers often distinguish between sweet (of low toxicity) and bitter (of high toxicity) cassava. It is important to realize that although many sweet varieties do have lower levels of cyanide there is no well-defined correlation between the sweet/bitter taste and toxicity (Cooke, 1978). Considerable care should thus be taken when introducing unfamiliar varieties of sweet cassava to be sure that it is indeed a low cyanide variety.

Should cassava containing cyanide be consumed, the body will attempt to detoxify it. This puts the body system under great strain and can pose a serious health problem.The problem is particularly serious in areas with a low intake of dietary iodine (in which case goitre can develop) and for consumers with a low protein intake.

The toxic glycosides of cassava are reduced to safer levels during traditional processing.

Toxicity is initially considerably reduced by peeling. The roots are then grated breaking down the internal cells and so releasing the enzyme which starts to break down the cyanogenic glycoside complex. This releases hydrogen cyanide. During the subsequent fermentation stage, almost total breakdown of the glycoside occurs and the final frying, roasting or boiling step drives off the hydrogen cyanide, leaving a safer, edible product.

Toxicity problems have also been mentioned with regard to certain varieties of potato. This is of less importance on a worldwide basis and traditional methods have been developed to make the product safer for human consumption. Toxic varieties of potatoes are most commonly grown at high altitudes, particularly in the Andes. After harvesting they are soaked in water which removes the toxic components. The leached potatoes are then suitable for further processing, most commonly into a dried potato product. This process is described in more detail in the relevent section of this book.

Principles of Processing Techniques

A number of operations are commonly used in the processing of root crops and a brief summary of them is included in the following section. The descriptions are not intended to be crop specific and fuller details will be found in the relevant sections on traditional and improved root crop processing.

Peeling

This involves the removal of the indigestible outer layers of the root and is traditionally carried out by hand although mechanical and chemical peelers are available for larger scale operations.

Drying

It has been noted that root crops have a high moisture content. The preservation of almost all processed rootcrop products depends on reducing the moisture to a level which prevents the growth of micro-organisms. Drying is a very simple, inexpensive and common method to remove water in root crops and so extend their shelf-life. A brief summary of the principles involved is included here. Specific drying technologies are

covered in later sections of this book.
Drying requires the transfer of moisture from the product to the air around it. Clearly both the quantity (air flow) and moisture content (relative humidity) of the air will affect the rate at which a product dries, as will the nature of the product itself.
It is important to realize that there are two stages in the drying process;
(1) removing 'surface moisture'.
(2) removing 'internal moisture' from within the material.
The relative humidity of air decreases rapidly as its temperature is raised and at the same time its water-absorbing capacity increases.
The rate of drying during the first stage is dependent solely on the ability of the air passing over the material to absorb and remove moisture.
Air flow-rate is more important than temperature but in areas of high relative humidity the air may need heating to lower its humidity to a level that allows it to absorb significant amounts of water. In general, air with a relative humidity of 75% or more, is not able to effect drying except in the earliest stages when the root is very wet.
The surface area of food exposed to the air is also very important. Slicing or chipping of the root crop will increase the surface area, and thereby reduce the drying time.
Once the surface water is removed, a second stage of drying begins in which water is removed from the interior of the material. The rate of drying in this second stage is dependent on the rate at which moisture can migrate through the tissue to the surface where it evaporates to the passing air. The migration is a slow process, so drying rates are lower than in the first stage of drying. The drying rate is dependent on the moisture content, and on temperature, rather than air flow.

Boiling and steaming

Root crops are often cooked by boiling or steaming either for direct consumption or as one step in a processing system. This does not preserve the crop, which is usually eaten soon afterwards, unless it is further processed. Boiling and steaming are also important in cassava processing to partially detoxify the material.

Frying and roasting

Many types of root crops are commonly prepared by frying in hot oil or roasting. Roasting is widely practised throughout Africa where traditional techniques include burying the whole root in hot ashes or holding it in front of a fire. In gari processing, proper roasting is important to ensure a good quality product. Both frying and roasting enhance the flavour of the root crop and most importantly reduce its moisture content - so extending its shelf-life.
When packaged properly, fried, crisp products can have a shelf-life of several months.

Grating

The action of grating into fine shreds is a step common to the processing of many root crops and facilitates other later steps in a process, for example, de-watering, drying or pulping. The process alters the texture of the raw material. Grating methods range from simply rasping the roots on the trunk-spines of palms as practised in the Amazon basin of South America, through simple hand graters to mechanized graters.

Pounding

Pounding changes the texture of the previously prepared root crop to a more palatable, paste-like consistency. The root is first peeled and softened by boiling or soaking. Traditionally a large pestle and mortar is used.

De-watering

De-watering as the name implies, involves the removal of internal liquid from the root crop by pressing. This process is most common in cassava processing being an important method of reducing toxicity. Traditionally, heavy weights are placed on the prepared root crop and the expelled liquid is allowed to drain away. In other traditional methods a squeezing process is involved.

Starch extraction

While starch can be extracted from any root crop the most common starting materials are potato and cassava. Industrially, starch is extracted by a combination of wet milling, sieving and either settling or centrifuging. Starch can also be extracted by more simple methods. The juice draining from cassava, for example, during de-watering may be collected and left to stand allowing the starch to settle. After decanting the liquid layer the remaining starch may be rinsed and further processed into flour by pounding or grinding and drying.

Grinding, milling and sieving

After preliminary processing, including slicing or shredding and drying, most root crops can be ground to a flour. Of all root crops cassava is most commonly processed in this way, the flour being used in many traditional dishes such as 'fufu'. Traditionally pestles and mortars are used for pulverization but on a larger scale, hand or mechanical plate or disc mills are more appropriate. After grinding, the coarse flour is sieved, with any large particles returned for further grinding.

Fermentation

Fermentation is a most important step in the processing of cassava and certain high alkaloid-containing varieties of potato. In both cases fermentation results in a reduction in the levels of the toxic components. In the case of cassava two methods are commonly practised, which may be conveniently considered as the 'dry' and 'wet' methods. The dry method is used in the production of 'gari' and is essentially fermentation in the presence of air. The grated cassava passes through a two stage fermentation. During the first phase, starch is broken down and acids are produced. Subsequently, breakdown in the cyanide containing toxic component occurs by the action of naturally occuring enzymes in the root so releasing hydrogen cyanide. The conditions at the end of this first stage then allow the growth of a range of micro-organisms that produce compounds that give gari its characteristic flavour. Much of the cyanide is lost during fermentation, the remainder being largely driven off during the final roasting step.

The simple 'wet' method of fermentation is carried out in certain areas of Africa and Latin America and is sometimes referred to as 'retting'. Wet fermentation takes place in the absence of air. Cassava roots, either peeled or entire, are soaked under water for several

days until they have softened. The material is then broken up, sieved and finally squeezed to remove water. Although culturally acceptable in many areas, cassava processed in this way has a somewhat unpleasant odour and the waters used in the process can be a source of pollution in streams.

Socio-Economic Considerations

In general, traditionally processed root crops are low-value products which do not normally justify improved technologies with higher capital costs unless losses can be greatly reduced or higher-value products made. When considering establishing or improving a root processing system a decision on the production scale and technology used must be made.

This decision will depend on:

- economic status of members of the community
- supply of raw materials
- labour requirements
- cultural obstacles
- organisational and management capabilities
- availability of markets, both local and distant

Economic status

It is a truism that no-one can control a technology they don't own. This is, however, often forgotten in project work, when technologies are introduced that could not possibly be afforded by the groups being worked with.

This economic status is not simply the money people have to spend but also their access to credit. Most people can obtain access to credit, of a sort, but usually at extortionate interest rates. Any economic calculations must take this into account. Commercial interest rates (eg, the bank rate in the capital) should not be used in calculations of rates of return unless the processors can really have access to money at those rates.

At the village level, payback periods of more than one agricultural cycle or year may be unrealistic because it means scarce cash resources will be unavailable for other, possibly more immediate needs.

Lengthy payback periods may prove to be an effective obstacle for poorer, more vulnerable households.

Raw materials

The supply of raw materials is particularly important. Technological improvements which require a high capital investment such as a motorized cassava grater, will necessitate relatively high and stable crop production levels in order to pay for themselves within a reasonable time period.

Local land ownership patterns may preclude the establishment of a sufficient area under root crop cultivation. For example, in parts of West Africa, the community is traditionally the owner of the land with the Chief allocating parcels of land to households as needed. In Sierra Leone, lack of regular access to fertile land to produce the necessary cassava supplies for a women's cassava grater group proved to be a major hindrance for expansion. In this case, competing requests for land needed to cultivate cash crops by their male counterparts resulted in the women's group receiving lower priority.

Labour considerations

Labour requirements must be considered when choosing a technology as they can vary for different crops at pre-harvest and post-harvest production time. When comparing expected labour demands for root crops like cassava and yams, cassava requires little labour and is very easy to cultivate whereas yams require considerable effort in such tasks as, for example, staking and drainage preparation. In terms of post-harvest production needs, cassava processing is perhaps the most demanding of all the root crops as it requires detoxification before becoming edible. Much less effort is required in processing yams, for example, which also have the advantage of being a relatively hardy crop that can be stored for several months before any processing is required.

Cultural obstacles

Group ownership and operation needed to share investment costs and make maximum use of a higher capital cost technology may meet local cultural obstacles. Women may need to ask their husband's permission to participate in work efforts outside the household. If the husband feels threatened by his wife's participation in an income-generating project or feels that her labour may be better used to support his cash activities, then this permission may not be granted.

In some areas or countries, women have a tradition of working co-operatively, but not of dividing tasks between themselves. The introduction of a technology that requires group co-operation may result in increased suspicion over pooled finances and fear of unequal compensation for labour input.

Organizational and management capabilities

If a new technology requires group organisation, then there are several key questions that the members of the group must address themselves to:

- how will decisions be made
- who will have access to the technology and on what terms
- how will the group be managed from day to day
- who will look after the money
- who will operate and maintain the equipment
- how to control misuse of funds or machinery.

As well as deciding on the constitution, the group will have to choose a manager, and she will have to be trained in her responsibilities and relevant skills. She must also be ready for much suspicion and must, therefore, be scrupulously honest. It is usual, and often unwise, that a village leader is chosen. She, or sometimes he, is often tempted to abuse his/her position, since no-one will speak out until it is too late.

Marketing potential

Processed root crop products such as cassava flour, flaked instant yam, breakfast and weaning foods, chip and snack products have been developed in response to an expanding demand from urban-based populations in developing countries. This has offered new opportunities for rural people to earn cash incomes from processing their root crops. These new products, however, while having great potential for adding value to rootcrops and providing income to rural producers, often have very limited

markets. Any introduction of a new product must be accompanied by market research and consumer testing.

Along with these changes in consumer preference by an emerging middle class, there are growing health dangers as a result of rising demand. For example, in Nigeria, increased demand for the fermented cassava product, gari, has resulted in less careful processing. The fermentation period in certain zones is usually two to three days which allows sufficient time for breakdown of toxic elements within the cassava. Some commercial processors have reduced this period to one day and have added lime juice to produce the preferred sour taste instead of allowing the production of the natural fermented taste to occur in the detoxification process.

Traditional Processing Techniques and Equipment

Traditional processing of root crops has developed to suit local situations. A whole range of processing techniques, equipment and products have been developed which vary not only from country to country but also within individual countries. It would not be feasible to describe all the variations that exist, so in this section we shall look at typical processing systems used in Africa, Asia and Latin America. A description of some traditional equipment is followed by an account of traditional processing methods covering the more common products in areas of the three regions. The products described are arranged by crop type. In view of the emphasis on cassava so far in this document this section will start by looking at some of the other important root crops. Prior to recommending methods for improving traditional processing systems it is essential to understand fully how and why they have developed, how they fit into local social conditions and the relevent food science principles outlined earlier. Simply being aware of traditional practices is not enough.

Traditional Equipment

The items described below are very simple, low in cost and available locally. These important factors determine the suitability of equipment to local processors. Most of the items have been designed for cassava processing because of the more elaborate procedures involved to make this crop safer to eat.

Peelers

Peeling of roots is commonly carried out using knives made of bamboo, flint or metal.

Graters

Examples of the wide range of traditional graters used particularly for cassava, include, in South America, rough stone, the prickly trunk of palms and shells. A stone or piece of wood covered with shark skin or sharp stones set in basketwork has been used in the West Indies. Graters made from flat pieces of wood into which splinters of thorn, teeth or fishbone are driven or embedded in a wax coating are used in Venezuela, parts of the Amazon and Brazil.
In Ghana, Nigeria and Sierra Leone graters are made from sheets of tin or iron which have been pierced with nails on one side in order to produce a rough surface on the other.

Presses

The 'Tipiti' is used in Latin America, particularly in Brazil, for de-watering cassava. It is a complex cylindrical basket press which is diagonally woven such that it can be stretched lengthwise to squeeze its contents. It is suspended from a beam or tree while the lower loop is weighted down with a stone, or a pole is inserted so that one can exert pressure by pulling. More simply, strips of bark are spirally wrapped around the grated cas-

sava and twisted to squeeze the contents.
Such devices are not found in Africa where bags filled with cassava pulp are commonly pressed with heavy stones.

Sieves

Woven baskets or suspended cloth pieces holding the mash are used to allow the liquid to drain away or separate excess fibrous material.

Pounding/Grinding equipment

In South America and Africa pestles and mortars made of heavy wood are used to pound both fresh roots prior to processing and also to produce flours. Some of these may be large enough to require as many as eight women pounding simultaneously.

Roaster

A whole range of systems are used to roast root crop products over a fire. Examples include pans, oil drums cut in half and specially constructed raised clay semi-circles common in Nigeria. As the material is roasted it is continuously turned with a wooden spoon or calabash.

Potato

Potatoes, unlike the other root crops covered in this sourcebook, grow best at temperates below 20°C. Production in developing countries is therefore concentrated in highland areas where the soil temperature is cool enough. Potatoes and their processed products are one of the staple foods of highland peoples such as those of the Andean areas of Peru and Bolivia.
Generally, potato is consumed fresh, that is to say by cooking the fresh tuber. However, this crop is seasonal and for supplies to be available out of season, it is necessary either to store fresh or to process it into a stable product. Dehydrated products such as 'papa seca' and 'chuño' which can have a storage life of several years have been traditionally made for centuries in the Andean areas of Peru and Bolivia.
Potato is more difficult to cultivate than cassava because a live tuber, or seed, is required for planting the following season's crop. This seed potato thus has to be carefully stored and is more perishable than the stick, or stem used for cassava cultivation.
As has been mentioned in the section on food science potatoes contain toxic complex alkaloids, termed solanines. The amount of solanine present depends on variety. Levels are higher in immature potatoes and particularly high in active growing parts of the plant such as sprouts. Bitter potatoes, with high levels of solanines are grown in the high areas of the Andes and these are made safer for eating by processing into products such as chuño, tokosh and tunta.
To summarize, the main constraints facing potato production and marketing in developing countries are its irregular yields, seasonality, availability of live tubers for planting and the perishability of the fresh tuber in normal tropical temperatures.

Traditionally Processed Products

Product	Chuño
Region	South America
Country	Peru
Equipment	Straw, rocks, sacks or pails
Process	Process requires particular climatic conditions with very low night temperatures (-10 to -20°C), high day temperatures (20-25°C) and low relative humidity. Many variations in technique exist, the following is a typical method.
Raw material	Usually bitter varieties of potato
Prepared	Laid on straw bed for 1 day.
Frozen	Potatoes laid out to freeze at night time.
Defrosted	The following day they are allowed to thaw and may be covered wth straw to prevent blackening. This freezing thawing process is repeated several times and causes rupturing of cells.
Treading	The potatoes are trampled so squeezing out liquid from the broken cells and removing the skin.
Soaking	Placed in a running stream for several days.
Dried	In sun for 27 - 30 days (10% maximum moisture)
Product	Chuño is consumed by soaking in water and then cooking in soups, or eaten with meat, cheese etc.
Advantages	Long storage life of up to 3 - 4 years. The process has the great advantage of not requiring fuel, a very scarce commodity in these high areas.
Disadvantages	Product dependent on climatic conditions (frost, cold running water, sun). Considerable loss of nutrients particularly protein and vitamin C.

SECTION 2

Product	Papa Seca (Dried Potato)
Region	South America
Country	Andean highlands in Peru and Bolivia
Equipment	Cooking pot, tin sheet or sack
Process	Essentially partial cooking followed by sun drying.
Raw material	Potatoes.
Prepared	Boiled and peeled by hand then sliced or broken into small pieces.
Dried	Sundried on tin sheets or sacks.
Product	The product is used in many traditional dishes.
Advantages	Useful method of utilizing smaller second grade potatoes. Has considerably more market acceptability than chuño, higher value product than chuño.
Disadvantages	Fuel is required for boiling.

Product	Potato Starch
Region	South America
Country	Peru
Equipment	Grinder, large jars, cotton cloth
Process	Pulping, washing and sun-drying
Prepared	The potatoes are peeled.
Pulped	Ground into a pulp, thereby breaking down the cell walls and releasing the starch. The resulting milk contains mainly starch together with minor amounts of skin and fibre particles. If the latter are not removed by washing and sieving a brown-coloured starch which has a lower market value will result.

Settling The ground pulp is diluted with water and left to settle in large containers. The starch settles to the bottom. After the liquid above the starch has been poured off the starch is re-slurried in water and again allowed to settle. This washing process is repeated several times until a clean white product results.

Drained The starch is drained by squeezing in a cotton cloth.

Dried Placed in the sun to dry.

Note: Very little traditional starch processing is now carried out at household level, having largely been replaced by maize and potato starch imported from Europe and the USA.

Yam

Yams are an important staple food in West Africa, the Caribbean, parts of Southeast Asia and the Pacific. In West Africa the yam 'zone' principally covers the Ivory Coast, Ghana, Togo, Benin and Nigeria with the last being the world's largest producer.

Traditionally, yams have an important cultural role. In the yam 'zone', it is commonly forbidden to eat the first yams of the new harvest until the annual New Yam Festival occurs. There is also a gender division associated with the handling of the crop. Generally, in West Africa and Melanesia, men control the growing and storing of the crop. Some women, especially widows, may grow and store yams. This is advantageous to women in West African communities where a well-built and stocked yam barn is considered prestigious. However, in Melanesia, the gender taboo is stronger, and women are excluded from all cultivation stages of one particular yam species (*Dioscorea alta*), but are allowed to cultivate other less important species. This particular species may have been designated the man's crop and attained ritual importance because of the high labour and financial investment required for its cultivation. Another cultural belief common in West Africa is that small tubered species are thought to produce an inferior 'fufu', and thus considered an inferior gift.

When compared to cassava, yam is a more difficult and expensive crop to cultivate. Labour inputs and material costs are higher as not only does a yam crop require more husbandry but also greater soil fertility. It is a seasonal crop and part of a live tuber is required as planting material for the next season. Because of the perishable nature of the planting material the farmer does not necessarily have the next season's crop secured. This means that the producer requires a well managed store and may on occasions have to purchase suitable planting material from elsewhere.

Some varieties of yams will store up to 6 months. There are well developed traditional storage systems in the major yam-growing regions. These may involve leaving the tubers in the ground or heaping freshly harvested tubers underneath rock outcrops, on household

floors, inside huts, underneath houses built on stilts or underneath soil and humus. Under these conditions the rate of deterioration is reduced by curing, which is described later under the relevant heading. In parts of West Africa special structures are built for the storage of tubers. These 'yam barns' consist of a vertical framework of timbers with cross pieces of bamboo or the ribs of palm leaves. Tubers are fastened individually to the structure using raffia.

Yams are usually prepared for eating using simple cooking such as boiling, baking, roasting, steaming or frying.

Throughout the West African yam zone fufu is the most popular processed yam product.

Certain varieties are preferred for fufu production as they form a stiffer dough.

In the Pacific Islands yams are wrapped in green leaves with other ingredients such as coconut cream and chicken or fish and roasted in ovens.

Although there are about 600 species of yams, only about 10 are edible, and many contain toxic alkaloids. Some toxic varieties are traditionally processed as in the Philippines where for example, the following technique is used:

- thin slices of peeled tuber are placed in a basket and submerged in the sea or a solution of salt water for 2-3 hours;
- the slices are removed and squeezed under weights for a few hours;
- the material is replaced in the basket and left in a running stream for 36-48 hours with occasional stirring.

Traditionally processed products

Fufu is one example of a whole range of sticky dough or porridge-like foods.

The name is often applied to any such product made from starchy material such as cassava, yam, cocoyam or plantain, either singly or in combination. It is also sometimes used to describe similar doughs made from cassava starch, cassava flour or grated cassava. Numerous local variations and methods of preparation thus occur. For interested readers an excellent survey is included in the *Further Reading* list (Lancaster, *et al.*, *Traditional Cassava Based Foods: Survey of Processing Techniques*.)

Product	Fufu
Region	West Africa
Equipment	Pestle and mortar, sieve, raffia or cotton bags
Process	Raw material pounded or mashed to make a heaqvy dough.
Raw Material	Yam, cassava, cocoyam or plantain or blends of these.
Prepared	Peeled and cut into smaller pieces.
Cooked	Boiled or steamed till soft.

Pounded In a pestle and mortar with a little water until a smooth, sticky dough forms, which is then ready for consumption.

Product A heavy dough.

Note: The preparation of fufu from 'bitter' cassava will differ: unpeeled roots are placed in streams or in large earthenware pots for 3-5 days for soaking and fermenting. The roots soften and the peel and central fibres may then be removed after which the product is ground or pounded in a mortar until a smooth soft mash results.

Product Yam Flour

Region West Africa

Country Togo, Ghana, Ivory Coast, Benin, Nigeria

Equipment Pestle and mortar, sieve, knife

Prepared Tubers are peeled and sliced to about 1 cm thickness and parboiled in water.

Dried After cooling, the pieces are sun-dried until hard. In this chip form, the product is referred to as 'elubo' in Nigeria.

Ground Ground into coarse flour with pestle and mortar although mills are used where available.

Sieved To produce a finer flour. Grinding and sieving is repeated until product is satisfactory.

Note: The flour can be rehydrated with water to form a dough as needed, but considered an inferior substitute for fufu.

Advantages:

(1) Flour can be prepared from damaged tubers, thus limiting crop and storage losses.

(2) Can be stored for several months provided that the moisture content is sufficiently low and the product is protected from insect and rodent attack.

(3) The dry chips can also be stored and ground to flour as required. This has the added advantage of giving greater stability to moisture absorption.

(4) Stable product allows for reduction in marketing and transport costs.

Disadvantages:

(1) Certain varieties of yam turn black or brown and can be extremely hard when dry. This has met with consumer resistance.

(2) 'Elubo' is very hard and difficult to grind using conventional milling machines and causes machine wear.

Edible Aroids

Aroids are physiologically similar to root crops, although they do not yield edible roots but swollen starchy stems. They are cultivated, processed and consumed as a dietary staple in a similar way to root crops. Many aroids contain irritant crystals of oxalic acid and special cooking methods have been developed to make them safe and palatable. Within the edible aroid group, taro and tannia species are the main food crops used for direct human consumption and will therefore be the subject of this section. Tannia, taro and allied species are often collectively known as cocoyams.

Cocoyam cultivation and processing for direct consumption is a subsistence activity. Again, the crop requires high labour and material inputs compared to cassava. Traditional processing methods are limited to boiling, mashing, drying and fermentation. Commercial production includes products such as weaning foods, flakes, breakfast foods, noodles, canned and frozen goods. Such activities which require cultivation to be on a larger scale are concentratd in Hawaii, the Philippines, the Caribbean Islands and Egypt. Although taro and tannia appear similar they have developed in different hemispheres. Both crops are important staples in West Africa, while in Oceania taro is preferred. Taro requires more careful processing than tannia to eliminate the larger amounts of oxalic acid present.

In West Africa, tannia is commonly boiled and pounded with other root crops into fufu, or eaten boiled, fried, or roasted. In Hawaii and southern China, taro is fermented to make a purplish - grey paste known as 'poi'.

Traditionally Processed Product

Product	Poi
Region	Pacific
Country	Hawaii
Equipment	Knife, grater, sieve
Process	Cooking and grating
Prepared	After cooking, taro is peeled, washed and grated.

Fermented	The resulting liquid mass is kept at ambient temperatures for several days to ferment, during which time lactic acid is produced.
Product	When fermentation has produced the desired taste the poi is ready for eating.

Sweet Potato

The sweet potato originated in Latin America and is now widely grown throughout tropical and sub-tropical regions, particularly in the Pacific, Carribean, East Asia and New Zealand. It is not generally eaten as a main dietary staple in the same way as cassava, maize or rice; that is to say with almost every meal. The research that has been carried out on sweet potato is mainly in connection with processed products for the crop in the developed world. In the U.S.A. it is canned, frozen, dehydrated or used in pie fillings, candied pieces and baby foods. This suggests that its potential in developing countries as an important processed food has perhaps not been fully realized. Sweet potatoes are comparatively easy to grow and have a high consumer acceptability. However, they have a short storage life, generally less than four weeks in the tropics. Their thin skin is easily damaged during harvest and post-harvest handling leaving the crop highly perishable. It is therefore usually consumed soon after harvesting. Alternatively curing, drying and fermentation are traditional preservation methods, some of which are illustrated below.

Traditionally Processed Products

Product	Chips
Region	East Africa, Asia (India)
Process	Slicing and drying
Prepared	Tubers are peeled and sliced
Dried	The pieces are placed in the sun to dry and can then be stored. When the product is needed for consumption the dried slices are washed and boiled or ground into flour for making local dishes.

Product	Flakes

SECTION 2

Region	South East Asia
Country	Philippines
Process	Drying, pounding
Prepared	The tubers are peeled and flaked.
Dried	Placed in the sun to dry and then stored. When needed for consumption the dried flakes are pounded into a flour and either made into gruel by mixing with water and sugar, or formed into small balls of a dough consistency which are wrapped in sugarcane leaves and boiled.

Product	Flour
Region	South America
Country	Peru
Process	Drying, milling
Prepared	The tubers are peeled and sliced.
Dried	Placed in the sun to dry
Milling	The dried slices are milled and sieved to produce a flour.

Product	Fermented Sweet Potato 'Poi'
Region	Asia
Process	The tubers are baked or steamed.
Prepared	After cooking the tubers are peeled and pounded with a stone pestle in a long shallow bowl of wood or stone.
Fermented	The sticky dough is mixed with water and left in a calabash to ferment for several days (depending on local tastes).

Product	Futali
Region	Africa
Country	(Malawi)
Process	Cooking, pounding
Cooked	Boiled or roasted.
Prepared	Pounded together with peanuts to form a paste.

Cassava

The majority of the total world production of cassava is processed for direct human consumption in Africa and South America. In Asia, Thailand produces cassava chiefly for industrial purposes and export. Such industrial applications include animal feed, alcohol, starch and food products such as tapioca and 'instant' mixes. Cassava processing is not only important for preservation of the product which, as has been mentioned, must be used quickly after harvesting but also to reduce its toxic components. The toxicity of cassava has been covered in the sections of this book on basic food science and technology.

Traditionally Processed Products

Product	Gari
Region	Africa
Country	Nigeria, Ghana
Equipment	Grater, roasting pan, sieve, jute or fibre bag
Process	Fermentation, roasting
Prepared	Washed, peeled and grated roots are placed in large cloth bag in the sun and left to ferment for 3-4 days. Weights are placed on top of the bag to press out the liquid which drains away.
Sieved	When sufficiently dry (about 50% water content) the pulp is removed from the sack and sieved to remove fibrous material.

Roasted	Small amounts are constantly stirred in a shallow pan over heat until cooked. Palm oil is sometimes added to prevent burning and to impart a yellow colour.
Cooled	Spread out to dry further and cool.
Product	A light, crisp, free-flowing granular powder which is creamy white in colour. Shelf life: few weeks or months to more than one year depending on packaging and moisture content. For safe storage, moisture content must be below 12%. Also known as "Farinha de mandioca" in Brazil which is somewhat different in that its fermentation and pressing time (due to use of the Tipiti press) is much shorter. The product also has a different taste.
Advantages	Usually eaten as a convenience food and is therefore attractive to urban markets. When packaged properly has a good shelf life.
Disadvantages	Grating and peeling are time-comsuming; frequent cuts on the hands with hand-graters. Constant stirring of gari over a fire requires processor to endure heat and smoke and exposure to an atmosphere of cyanide gas for lengthy periods of time.

Product	Landang or Cassava Rice
Region	Asia
Country	Philippines
Raw material	Cassava
Equipment	Grater, jute sacks, winnowing basket, sieve, mat.
Process	The following are two common methods used to prepare this traditional Philippine dish:
Method 1	
Prepared	Freshly harvested roots are peeled, grated, and placed in jute sacks.
De-Watered	The sacks are pressed between two wooden blocks to squeeze out the juice.

Pelleted The pulp is put into winnowing baskets and whirled until pellets form (size depends on speed of motion and moisture content).

Sieving Pellets of more or less uniform size are isolated by sifting — those too big to pass through the sieve are broken, put back in and whirled again.

Steamed The pellets are steamed on a screen mesh placed over a vat of boiling water.

Dried After being separated by hand while still wet, the pellets are finally sun-dried on mats.

Method 2 Peeled roots are soaked in water in earthenware jars or wooden containers (contact with metal should be avoided) until they begin to soften (5-7 days). The contents are macerated and fibres removed by hand. The mass is air-dried, before making the pellets as described before. In both methods the pellets are thoroughly sun-dried for 3-5 days before storage. The product can be eaten without further cooking, or can be soaked, mixed with coconut milk, reboiled and served.

Advantages If placed in a cool, dry place, the storage life is 3 -6 months. Considered ideal for fishermen and others on trips as it stores well and can be eaten without cooking.

Product Gaplek (Cassava Chips)

Region Southeast Asia

Country Indonesia

Equipment Jute Mats

Process Drying

Prepared Peeled and cut into thin slices.

Dried Spread on woven mats or hung on fences to sun-dry. The drying time varies with the amount of sunny weather, but it is normally 2-3 days. The chips are sometimes steamed before drying, which it is reported prolongs the storage life.

Product Cassava chips are usually further processed as needed for consumption: boiled, fried in oil, or ground into flour.

Note: Preparation of cassava into dried chips followed by further processing into flour when needed is widely practised in Asia.
In Thailand and Indonesia cassava chip production is also carried out at the commercial level, being a primary export.
In India the chips are parboiled before drying. Storage life can be up to one year compared to 3-6 months without parboiling.
In Ghana, the smaller whole roots which might otherwise be discarded are peeled and left in the sun for approximately 10 days to dry. This product is known as 'Kokonte'.

Product Cassareep (West Indies)
Tucupy (Brazil)

Region South America and West Indies

Equipment Grater, press or "Tipiti"

Process Extraction, concentration

Prepared Roots are peeled and freshly grated.

De-watered Pressed to obtain juice which is collected.

Evaporated The liquid obtained is boiled down and concentrated by evaporation until it reaches a dark, syrupy consistency. The long heating destroys the toxins in the juice.

Product A thick syrupy sauce.

Note: Along the Caribbean coastal areas, cassareep is the basis of the traditional dish 'pepper pot' in which all kinds of meat, fish and vegetable leftovers from meals can be placed and cooked. Cassareep is said to be a meat preserver and pepper pots can be kept for many years by adding further ingredients as necessary and bringing to the boil daily. Bitter varieties of cassava are considered to give the best quality cassareep.

Advantages Long-storage life

Product Cassabe. This one example of the many types of cassava bread traditionally produced in many countries.

Region South America

Country Venezuela

Equipment Tipiti press, sieve, iron plate or griddle, trays

Process Grating, drying, baking.

Prepared Two methods are used depending upon whether the roots are subjected to a soaking fermentation stage or simply peeled and grated.

De-watered The juice is squeezed out from the mash using a Tipiti. The resulting 'press cake' is left for several hours or overnight until it becomes quite solid.

Sieved The cake is broken up and rubbed or sifted through a coarse sieve to separate out extraneous fibres.

Dried The dough is pressed down to a thickness of 1 cm in wide trays made of woven palm fibre and left in the sun until completely dry and hard.

Baked The press cake is either sun-baked or baked over a fire. Alternatively, the sifted pulp is spread into thin flat cakes and cooked on a hot griddle, turning to cook both sides to produce a hard cake. The cakes are then dried in the sun on the roofs of houses until they become hard. The cakes so produced can be 2 to 3 feet in diameter; pieces are broken off and dipped in gravy and soups.

Note: Cassabe or cassava bread is the staple diet of the Amazonian Indians. Bitter cassava is preferred as it has a higher starch content which makes the product less brittle and better to store.

Advantages The hard, brittle cake keeps in good condition for easy storage for several months, a convenient food to carry on extended trips such as when hunting.

Disadvantages A laborious process which can take up to 2 days

---

Product Cassava Beer

Region Widespread, including Central and East Africa and Latin America.

Equipment Earthenware jars

Process Kasiri is one example of a common fermented alcoholic beverage based on cassava.

Method 1

Prepared Fresh tubers are left up to a week in a flowing stream until detoxified by fermentation.

Fermented The fermented cassava is removed from the stream, put into a jar and water is added leaving it to stand for another 3 days after which the mass is heated. In some cases yeast is then added before allowing the fermentation to continue.

Method 2

Prepared This process is widely used throughout Central and South America, and the West Indies. Cassava bread is chewed up, mixed with water, and fermented for 2-3 days. The natural enzymes of the saliva speed up fermentation by initiating the breakdown of starch to sug ar. Traditional customs require that only young girls chew the cassava in some areas while only the oldest women are permitted to do so in others. Without chewing, fermentation takes 4-5 days.
The drink has ritual importance for some tribes in the Brazilian tropical forest.

Product Starch

Region South Pacific

Country Tonga and Western Samoa

Equipment Knife, bucket, grater, strainer, mats

Process Extraction, drying

Prepared Fresh roots are washed, peeled and grated into coarse meal.

Extracted Grated cassava is washed with water, strained through a cloth bag which is squeezed by hand to extract starch

milk. This is then poured into a bucket or basin. The process is repeated until the squeezed liquid is no longer white.

Decanted After standing for several hours the starch will settle to the bottom.

Washed The starch is washed and the procedure repeated until the liquid poured off is clear.

Dried The white starch remaining at the bottom of the basin is removed and spread out on mats to dry in the sun.

Product When almost dry it is pressed into balls or dried completely and pounded into powder.

Note: Traditionally, starch was made from arrowroot, or sago palm. Since cassava is cheaper it has tended to replace these starches.
The most common use is to add to puddings or mix with fruit. Cassava starch can be stored as needed. It is baked into cakes in the Caribbean, Pacific Islands and Jamaica. Cassava starch can be further processed into tapioca: wet starch is heated in a pan stirring continuously until the grains burst and gelatinize into globules.
In West Africa starch is traditionally processed, dried, rehydrated later and eaten as pap or porridge.

Traditional Curing Methods

The purpose of curing is to increase the storage life of the tuber. During curing, conditions of increased temperature and humidity encourage growth of the outer layers of the tuber's skin. Existing wounds are thus sealed preventing entry of micro-organisms thereby helping to inhibit deterioration. Curing is practised with cassava, sweet potato and especially with yams. Several curing methods are described below.
In Papua New Guinea the tubers are stacked on platforms in a dark area of the house where heat and humidity from the cooking area can cure them. On the other hand, the Maoris of New Zealand practise pit storage as a method of curing sweet potatoes. Here, underground storage pits are dug into the side of a hill and the floor of the pit is covered with a layer of gravel and soft packing.
The seed stock is placed in first to fill the back of the pit while the tubers for consumption are stacked at the front, being separated by fern leaves. The store is sealed to allow a build up of heat and humidity inside for curing (owing to the natural respiration of the tubers).
Pit storage is also practised in Zimbabwe and Malawi. Yams are usually cured by covering the tubers with earth.

Improved Processing Equipment and Products

Many of the traditional processing systems outlined in the previous section have been improved and in many cases mechanized.

When considering upgrading traditional methods or introducing improved technologies, it is important to be sure

- that the need is correctly identified
- that appropriate expertise (including technical, socio-economic, marketing etc.) is available.

The introduction of improved technologies for root crop processing has met with varying degrees of success. Mechanical peelers, for example, have in some cases resulted in higher wastage than hand peeling and in general have not proved acceptable in small processing units. Graters on the other hand seem to have met with wider acceptance being able to take over what is seen as a very laborious task.

Complete 'packages' of equipment, of various scales are available for processing several rootcrops. Comparatively small packages exist for example for carrying out all the process steps in the production of gari and secondary cassava products such as chips, instant mixes and breakfast foods. Some of these products are not part of traditional local foods and are too expensive for most villagers.

They therefore have little or no readily available rural market.

Most small rural villages do not have the facilities to meet the necessary requirements of high capital investment; a regular and formal labour force; access to, and a regular supply of production materials and management abilities necessary to operate larger scale plants. For this reason package systems available will not be covered in this text. There appear to be few, if any, cottage or small-scale mechanized 'packages' for processing a particular rootcrop.

This section will describe improved technologies by processing methods and will include:

- Peeling and Washing
- Grating and Rasping
- Pounding
- Pressing and De-watering
- Sieving
- Roasting
- Drying
- Milling and Grinding
- Chipping and Slicing

As it is not known which pieces of equipment used in these processes are still prototypes, have been tested in the field, or are actually being used by rural women at village level, the names and addresses of the equipment suppliers and appropriate institutions are given in section 7 as a first contact point.

It should be stressed that before considering obtaining any equipment it would be beneficial to consult appropriate institutions (listed in the Contacts section), especially those who have had previous experience in introducing the equipment.

The introduction of an improved technology or process may benefit a community both economically and socially.

Increasing the efficiency of a process by making it more cost effective with the aim of increasing incomes will also result in social change, which will have to be acceptable to those involved. Both economic and social factors therefore need to be considered, ie:

A. Economic

1. Availability of local workshop facilities to produce or maintain the improved production system.
2. Labour requirements and availability.
3. Raw material supply.
4. Scale of production desired.
5. Production and product cost. The product may have to competeeconomically with traditional products made using uncosted or low-costed family labour.
6. Potential consumer markets.
7. Access to credit at local interest rates.

B. Social

1. Family needs and capacity for labour and/or capital investments.
2. Existing infrastructural support i.e. transport and credit conditions.
3. Cultural restrictions - gender divisions, local preferences in taste, texture, colour and odour of food, taboos, social structures.

Consumer acceptability is vital for a food processing operation to market its products. It is necessary then to examine and compare any change in terms of flavour, colour, texture and odour that might have occurred with the introduction of an improved technology.

Peeling and Washing

While equipment for washing and peeling root crops is commercially available its cost and throughput is generally too high for small rural projects.

Washing machines generally consist of a cylinder fitted with paddles and brushes that can be rotated while a stream of water is played over the rootcrop as it passes through the unit.

Mechanical peelers operate by rubbing the roots against a rotating abrasive surface. They are best suited to raw materials of regular shape. Irregular materials either have high losses on peeling or require final hand peeling. The use of mechanical peelers is dependent on the throughput required and local wage rates. In Europe, with its high hourly labour costs for example, the cost of hand peeling would far excede any losses of yield through mechanical peeling. It should be noted that in some cases abrasive peelers may offer a reduction in losses compared to hand peeling, especially when used for small roots or tubers.

A description of a simple washer and peeler that could be constructed locally together with a commercial peeler are included together with an outline of a chemical peeling process.

CIP Manual Potato Washer

The International Potato Centre (CIP) in Peru has designed a simple, hand-operated potato washer. A 55 gallon oil drum is cut lengthwise and paddle wheels equipped with brushes are fixed on an axle with wooden dowels. A handle is fixed to the axle in order to rotate the paddles and so agitate the potatoes. The washer has a capacity of 25 Kg of potatoes and requres 150 litres of water per batch. After a few minutes the drum is turned on its side to empty the potatoes and dirty water.

CIP Belt-Driven Motorized Peeler

A sheet-metal cylinder or 55 gallon drum whose surface has been punched from the outside to create an abrasive surface internally, is mounted on a horizontal axle. The drum is rotated via a belt-drive from a motor. Potatoes are fed into the drum from the top, and as the cylinder rotates the protruding holes scrape the skin from the surface of the potatoes. Each end of the cylinder is fitted with a small door so that the potatoes may enter at one end and leave from the other when peeling is complete. A perforated metal pipe set above the cylinder sprays water over the rotating drum. 20 Kg of potatoes can be peeled in 4 minutes. Final trimming and peeling is necessary. A smaller hand operated peeler can be constructed using a similar design.

Abrasive Plate Peeler

The 'Crypto Peerless' abrasive plate peeler is an example of a typical commercial machine in which a rotating abrasive plate rubs the skin from the material passed through. It is most commonly used to peel potatoes. Various sizes of such machines are available from as small as 13 kg/batch. They are powered by electric motors.

Lye Peeling

Hot solutions of sodium hydroxide (lye) can be used to loosen skin of many rootcrops to facilitate later peeling, such as removal by water spray or scrubbing with brushes. A combination of chemical reaction and thermal shock aid in softening and loosening the skin. The desired effect can be obtained by selecting the combination of lye concentration, temperature and immersion time. Generally, lye acts more vigorously at higher temperatures. Technical advice should be sought if lye peeling is being considered, as problems can occur. For example, partial cooking and gelatinization of the outer layers of the root may, cause too much lye absorption. In addition, sodium hydroxide is a very dangerous chemical to handle and workers need to be properly trained and protected. In addition the used lye solution is a potential source of pollution and can corrode equipment. The following table shows suitable combinations found for the lye peeling of yam:

Lye Peeling of Fresh Yams

Table 3

Relation between immersion time and lye concentration on the efficiency of the lye peeling operation

Lye concentration Percent by weight	Time of immersion Minutes	Visual evaluation (1)	Loss in weight of lye-peeled tubers (2) Percent
10	2	Questionable	5.6
	3	Questionable	11.11
	4	Questionable	12.78
	5	Good	14.44
	6	Very Good	17.50
15	2	Questionable	7.22
	3	Questionable	11.11
	4	Good	13.33
	5	Very Good	16.11
20	1	Questionable	6.67
	2	Questionable	8.89
	3	Good	12.21
	4	Very Good	13.33

(1) *Questionable*: Tubers retained large patches of peel or many small patches.
Good: Tubers with one or two small patches of peel which can be removed easily by trimming.
Very Good: Tubers completely peeled.

(2) Average of three runs.

Lye Peeling of Fresh Yam, J.M. Rivera-Ortiz and M.A. Gonzales, 1972, 56 (1), Page 59.

Grating and Rasping

Grating and rasping are common steps in the processing of cassava and are time consuming and hard work. A considerable number of graters exist which range from simple hand graters through pedal operated units to motorized versions. Many are based on a rotating horizontal disc or vertical drum grating surface against which the root is held. Care should be taken when introducing any powered device that injuries do not occur: for example loose clothing becoming tangled in the drive, or fingers being caught in the rotating disc.

Hand Graters

The two selected designs of hand graters shown here are both low-cost and can be constructed of tin or galvanized mild steel. The grating surface is created by puncturing the surface with holes, as in traditional construction. Both models need only one operator and are probably most suitable for an individual family or to be shared amongst a few families.
This design is essentially an upgraded traditional technology, with the grating surface horizontal instead of at a downward slant, often supported against the processor's legs. The elevated grater is now supported on a table.

This hand-operated machine incorporates a rotating cylindrical grater against which the root is pressed. Note that only one tuber can be inserted at a time.

ITDG Pedal-Operated Cassava Grater

In the early 70's, an engineer at the Intermediate Technology Development Group's (ITDG) workshop in Zaria, Nigeria developed a cassava grater made from galvanised iron tubing, spare bicycle parts, hacksaw blades and sheet metal. Cassava is fed in the hopper and a vertical disc with grating slits fixed to a frame is rotated by pedal power.

Wadwha Disc Grater

This grater, developed in Ghana, consists of a disc-shaped wooden block to which is nailed a perforated metal sheet. The perforated disc is rotated by a belt drive from a 5 h.p. diesel engine. The throughput is one tonne of cassava per hour.

TAEC Vertical Drum Grater

This drum grater was developed by T.A.E.C. (Tikonko Agricultural Extension Centre) in Sierra Leone. The surface of the drum is covered with a sheet of perforated metal which rotates across the base of the feed hopper The cassava is pressed against the grating surface by a wooden block inserted in the throat of the hopper. The drum is rotated by belt drive from a 4 h.p. diesel or electric motor. The hopper, drum, and frame can be made from timber or scrap metal.

Pounding

The pounding of fufu from yams and cassava to produce a gelatinous, sticky product can take up to one hour using a traditional pestle and mortar.

Attempts to produce pounded yam products by rehydrating yam flour have proved unpopular because both the texture and taste were inferior to traditionally-pounded yam.

Motorized Pounding Machine

A machine for pounding yam and similar foods has been developed at the Department of Agricultural Engineering, University of Ife in Nigeria. It consists of a beater and bowl which operates in a manner rather similar to a heavy dough-mixer. The leading edge of the beater was sharpened to provide an additional chopping effect, with further beating producing a soft consistency characteristic of pounded foods. As in the traditional process water is added as necessary during the process. The unit is powered by a 1.75 h.p. motor and can produce enough fufu for eight adults in 45 seconds.

Pressing and De-watering

The common pressing step that occurs in several traditional root crop processing systems can remove up to 50% of the water present. Several press designs exist ranging from the simple, easily constructed parallel press board, press frame or wedge press to more sophisticated screw and hydraulic presses. The later clearly require access to better equipped workshops.

TAEC Upgraded Traditional Press

The traditional sticks-and-rope press has been upgraded by the Tikonko Agricultural Extension Centre in Sierra Leone. Two wooden frames are placed below and above the sacks filled with cassava mash. Half a dozen threaded rods pass through the bottom frame to fit holes in the top frame. Tightening exerts pressure on the sacks by pressing the frame closer together. The actual pressing time is not reduced but rather the time and labour necessary to either gather and heap heavy stones or to assemble and tie up the sticks around the sacks is reduced. Only wood, bolts and threaded rods are needed.

TCC Parallel Board Press

The Technology Consultancy Centre (TCC) in Ghana has developed a parallel board press which provides uniform pressure to pulp-filled sacks placed between them. Instead of a wooden frame as in the TAEC upgraded traditional model, two solid parallel boards are screwed together to create the pressure on the sacks. It takes about 3 to 4 hours to de-water one bag (125 kg) of gari as opposed to 3 - 4 days needed by traditional presses.

Wedge Press

The wedge press is an adaptation of a traditional Chinese press used to extract oil.

Tree stumps or wooden logs provide support for a wooden beam inserted in between them. Sacks of grated pulp are placed on the beam and pressure is applied when wooden wedges are hammered into the space between the sacks and tree stump.

Screw Press

Screw-type cassava presses can either be in the form of a circular press cage holding the fresh pulp or a square frame exerting pressure on the sacks. Both types work by moving a heavy circular or square block which is lowered or raised by means of a threaded shaft. The press cage has a capacity of approximately one bag (125 kg) of cassava per batch whereas the other design can handle several sacks of pulp. A lathe is needed for cutting the screw thread as well as metal bending and cutting equipment.

Hydraulic Press

Some designs of press use a hydraulic car or lorry jack to apply pressure to the material being dewatered, usually between pressing boards. If discarded car jacks are not available, the imported jack can make it an expensive piece of machinery to produce and maintain. Compared to the screw and other presses it requires the least amount of human effort to operate.

Sieving

After the pulp is de-watered by pressing the residual cake is traditionally broken up by manually rubbing it against wire mesh or raffia sieves. This process can be mechanized using either a vibrating or rotating sieve.

Improved Pulverizer and Sifter

The University of Nigeria has developed a prototype sieve unit which cuts up the cake into small pieces which then pass on a conveyor belt to a vibratory sieve. Output is 125 kg per hour.

Rotating Drum Sieve

AGRICO Ltd in Ghana have developed a unit made from a 44 gallon drum fitted with a cylindrical sieve made of wire netting. The cake enters through a hopper and is then sifted when the drum is rotated, exiting from the bottom. A power-operated version has been developed by the same company which is driven by belt drive from a small motor.

Roasting

Gari is traditionally heated in shallow cast-iron pans over a fire while being pressed and stirred against the hot surface with calabash pieces to prevent burning. Improvements have included either upgrading the traditional pan and wooden stirrer or development of a rotatable cylindrical roasting drum.

Upgraded Gari Roaster

One example is a rectangular tray roaster developed by The Rural Agro-Industrial Development Scheme (RAIDS) in Nigeria. A chimney helps to draw air which reduces the effects of smoke and heat on the processor. A long wooden stirrer or rake is used to turn the cake, preventing it from sticking and burning. This upgraded system improves the operators' health because the smoke is channelled away from the processor and the long stirrer allows her to remain some distance from the fire.

AGRICO Roaster

AGRICO in Ghana have developed a prototype cylindrical roaster containing paddles which continously stir the gari as the drum is heated. It can be hand or mechanically driven and heated by either wood or gas.

Drying

Technology choices exist for drying root crop products ranging from basic traditional systems which could consist of hanging the material from sticks right through to forced air driers. We have already seen, under Gari roasting, one traditional method of drying. This section will cover drying devices in the more accepted sense and include examples of solar, kiln-type and forced air driers in order of increasing sophistication, expense and drying capacity. Although these represent the range of drying technologies available, they have not been widely used for root crops. Root crops and their products are of fairly low value and it is doubtful that the use of artificial dryers would be economic, unless specialist comsumer markets exist requiring dry products with considerable value added eg, potato crisps or snack foods.

Solar Dryer

Simple solar dryers glazed with a transparent top and a system of air vents located at the bottom and top of the side are often referred to as Brace driers. The air in the chamber is heated by the sunlight passing through the transparent lid. The heated air rises and exits at the top of the dryer at the same time carrying away moisture from the product. An air flow develops with fresh air entering through the lower vents. While Brace driers are comparatively cheap and have been tried in many situations around the world they do not seem to have received wide acceptability.

Kiln Type Dryer

Two designs of simple wood fired driers are shown. In the first,sometimes known as a Brook Drier, a large tray is supported on a block or mud-brick base which has air entry holes in its sides. A flue passes under the tray through which hot air flows from a firebox to a chimney. Air entering the side vents is heated by passing over the flue. The McDowell drier is similar except that a transparent tent-like roof structure above the tray allows solar drying to be used when appropriate.

Milling and Grinding

Lumps often occur in gari if the heat is not distributed evenly during roasting. These large lumps will remain after traditional sieving process and are normally sold as animal feed. In order to reduce waste (losses of up to 10% can occur), roasted cassava can be milled in a conventional corn mill or hammer mill to reduce the lumps to a finer grade. An example of a hammer mill and a plate mill is shown below.

For further information on milling and grinding equipment, please refer to TOOLS FOR AGRICULTURE, ITDG.

Plate Mill

Hammer Mill

Chipping and Slicing

Slicing of root crops before drying reduces the drying time by exposing more surface area to the air. Slicing is also of course an important step prior to cooking root crops as it allows more rapid and even heat penetration.

DAC-FS Root Crop Slicer

The Department of Agricultural Chemistry and Food Science (DAC-FS) in the Philippines have designed a simple slicer which is said to cut sweet potatoes much faster than manual methods. The sweet potato is held on the cutting platform against a plate which controls the thickness of slice cut. Slices are then cut off with the hinged cutting blade. Capacity is 21 - 23 Kg/hour.

CIP Hand Operated Potato Cutter

The International Potato Centre (CIP) have designed a cutter which consists of a horizontal rotating cutting disc. The potato is pressed down against the disc with one hand while the other hand turns a handle thus rotating the disc. This machine has been modified for motor drive with the disc running in a vertical plane. Cutting discs can be changed to alter cutting thicknesses if required. Crypto Peerless, (whose address is listed), supply a similar motorized machine with capacities up to 600 lb/hr which slices, dices, chips, grates and shreds.

Nardi Root Cutter

Nardi Francesco and Figli of Italy produce a manually operated root-chopper containing a rotating disc fitted with four blades.

Pedal-Operated Cassava Slicer

To summarize, Table 4 outlines a comparison of traditional and improved technologies for gari processing.

P.T. Kerta Laksana of Indonesia has made a pedal driven cassava slicer fitted with one large slicing blade. It is claimed to have a capacity of up to 500 kg/hour.

Table 4

A comparison of three technologies for the production of gari

Stage	Traditional Labour intensive	Post-traditional Intermediate	Modern Fully mechanised
1. Raw material production and supply	Small holder production Yield: c. 10 (t/hectare/yr) From traders	Smallholder production Yield: c. 10 (t/hectare/yr) From traders	Factory plantation and/or smallholder cooperative Yeld: c. 10-25 t/hectar/yr From purchasing agents on factory plantations.
2. Peeling and washing	Manual: 38 kg/man hour 25% raw material loss	Manual: 38 kg/man hour 25% raw material	Mechanical abrasive peeler, 30% raw material loss.
3. Size reduction	Manual: 23 kg/man hour Mechanical: 200 kg/hr	Manual: 23 kg/man hour Mechanical: 200 kg/hr	Mechanical: hammer mill (imported), 1500 kg/hour
4. Fermentation	Fermentation and dewatering in heavily weighted cloth or nylon bags	Batch fermentation in (aluminium) tanks	Batch fermentation in (aluminium) tanks
5. De-watering	See 4 above	Semi-mechanised: locally made hydraulic or mechanical press	Mechanised: hydraulic press
6. Screening	Manual: woven fibre screen	Semi-mechanised: locally made screen with hand or mechanically driven paddle	Mechanised: motorised rotary screen
7. Garification	Manual; cast iron pan over wood fire (combined stage with drying): 2.2 kh/man hr	Semi-mechanised: locally made wood-burning fryer (combined stage with drying): 70 kg/man hr	Mechanised: rotary kiln heated by oil burners 450 kg/hr.

Stage	Traditional Labour intensive	Post-traditional Intermediate	Modern Fully mechanised
8. Drying	See 7 above	See above	Mechanised: rotary drum drier
9. Milling and sieving	Not necessary Sieving: locally made	Milling: not required Sieving: vibrating hand or mechanical sieve.	Milling: disc mill Sieving: vibrating multi-deck sieve
10. Packaging	50 Kg jute sacks	50 kg heat sealed poly ethylene bags	50 kg heat sealed poly-ethylene bags
11. Material handling (all stages)	Manual	Manual, with trolleys	Belt conveyors, bucket elevators with trolleys.
12. Marketing and distribution	Through traditional gari trade system in local markets	Through traditional trade system and super markets	Through traditional trade system and supermarkets
13. Purchasers	All income groups, rural and urban	Mainly urban higher income groups and institutions (eg schools, army)	Mainly urban higher income groups and institutions (eg schools, army)
14. Buildings	600 m^2	200 m^2	650 m^2
15. Employees per shift			
total	234	45	28
unskilled	229 Predominantly female	40	9 Predominantly male

Case Studies

Traditionally, the processing of root crops uses simple tools and methods, is highly labour intensive and has low labour productivity. It is not surprising that time is, therefore, a major constraint for women practising traditional technologies.

These case studies illustrate a number of the problems that can arise when trying to upgrade these traditional activities.

The case study from Sierra Leone illustrates that one must consider the entire system, from cultivation to processing, before attempting to introduce improvements at any one stage in the process.

A common problem arising in technology dissemination is that men often have more access to cash activities in rural communities than women. Unless a credit scheme is provided with the technology, its high purchase cost will provide an effective constraint on women benefitting. The case study from Ghana introducing gari-processing technology provides an example of this.

Mechanization can displace women from traditional income-earning activities. In Sierra Leone, the gari grater provided such an attractive new income source that the women's group lost control over the operation of the machine to the traditional village leader. This case study illustrates how vital it is to investigate the socio-political structures operating in a community when planning a project.

When considering ways to improve processing activities not only must the complex socio-economic environment be examined but also the infrastructure that may be needed to support the availability and diffision of improved technologies for women.

The case studies in this Section seek to provide an overview of the experiences gained in introducing improved root crop processing technologies.

Due to the lack of documentation on impact of projects introducing the full range of root crops and technoiogies, the case studies primarily cover cassava processing where the often high returns to gari production have encouraged technology innovation.

One case study from Papua New Guinea has been included which describes a sago palm processing project. Although sago palm is not a root crop, it is included because its lessons can be applied to many root crop processing activities. It shows clearly that introducing a new technology is not always necessary: transferring a traditional process from one area to another can work well given the availability of raw materials and markets.

1 Diesel-powered cassava grater - Sierra Leone

Summarized from:

Profile of Women in Farming Systems, Bo-Pujehun Rural Development Project Occasional Paper No. 4 February 1986, *"Gari Industry in Bo-Township"*, Bo-Pujehun Agricultural Programme, Report Series No. 23, Dec. 1984 and Private Communication (Linda Adams).

The Women's Programme of the Bo-Pujehun Rural Development Project operating in the Southern province of Sierra Leone introduced diesel-powered cassava graters on a pilot basis to selected villages beginning in 1984. The vertical drum graters were built locally at the Tikonko Agricultural Extension Centre (T.A.E.C.) in Bo using timber and scrap metal. The 4 h.p. diesel engines were imported from Germany and represented the most expensive part of the machine.

Gari processing is a highly profitable activity. In times of rice shortage (the staple food) and for urban populations which are dependant on village farms for their supplies of rice, gari is a popular food. Gari has a high value compared to fresh cassava because it has a considerably longer storage life and transport costs are a small proportion of the value of the final product.

In a pre-feasibility study conducted in Bo town in 1984 by the project, it was seen that 23% of the gari producers in the area were men. Normally, gari processing is considered a women's activity in rural villages and such a high percentage of men was seen to be due to the product's high profitability and the availability of improved technology in town centres.

Cassava processing in towns is usually done by hired motor-driven graters. Investment in a motor grater for the sole purpose of hiring it out is common. Given the domination of gari processing by women, it is ironic that only a small minority of women producers are owners of motorised graters.

This pattern of imbalance has been addressed by the Women's Programme by designing projects to improve women's access to improved technology, especially in the rural areas. A pilot project was initiated whereby motorised graters were introduced on a co-operative-ownership basis in rural areas. A revolving fund was set up by the Women's Programme at a national bank whereby women's groups could get loans with flexible repayments. The purchase price of the grater was also subsidised by the project.

The revolving fund system allowed village women greater access to formal banks in that the collateral of project funds made women to be seen as less risky borrowers to bank officials. In addition it gave the women an opportunity to learn about formal lending systems normally outside their experience. The flexibility of the payment schedule was adjusted to the seasonality of cassava production and the processors' other competitive labour obligations on the farm. This unique scheduling took into account the women's needs and was designed on a group by group basis.

The profitability of cassava products has led some farmers to shift production decisions in favour of cassava planting. In some villages located near to main roads allowing easy access to the capital city, almost the entire farm area was cropped with cassava and villagers used the proceeds from the sale of gari to buy rice and other staple foods. These changes have led to concerns over land being taken away from rice production in some areas and a general reduction of women's access to land for growing traditional food crops.

This interest in cassava has also led farmers to seek improved varieties. The women processors complained that the introduction of larger rooted improved cassava varieties with high water content resulted in an increased demand for fuelwood and subsequent processing time. Here is an example where the labour demands at different stages in the production cycle from cultivation to processed product were not taken into account by project planners and research stations. Although this particular

variety was higher yielding and therefore more productive at the cultivation stage, labour demands were increased at the processing stage as a result of its introduction.

Another environmental factor which affected the pilot groups was that competing development agencies operating on different terms were working in the same areas. This caused great confusion for villagers seeking access to the grater technology as the graters were offered at different subsidized rates and in one instance were given out free thereby discouraging self-sufficiency. One solution to this problem was that project managers met together and agreed on areas of operation.

Co-operation of group members was seen as critical to the success of the project. Before a loan could be applied for, adequate cropping areas of cassava had to be provided. In some cases this meant women farmers agreeing to put together their individual land holdings. In other cases it meant that the women in a village would organise a group together, request a piece of land from the chief, and agree to a communal work day each week on this land outside their individual household obligations.

Once the grater was set-up and in operation, decisions had to be taken as a group for new members who wanted to join or old members who wanted to leave and needed compensation. Other issues which arose included: on what terms members and non-members could have access to the machine; what penalties would be enforced for those not coming to group meetings, communal work days, or contributing membership dues/in-kind payments towards the loan. Such co-operation requires relatively high management capabilities within the group. It was observed that the profitability of gari resulted in women processors leaving cassava cultivation in some villages, as it was recognised as a new cash crop for their men. In such cases, these women returned to more intense cultivation of vegetables for their income source.

In other instances cassava cultivation was turned into a 'joint activity' with men controlling the proceeds. Women without husbands would cultivate cassava alone, that is if they had the cash resources to hire labour. In this area married women were usually not allowed to keep separate cassava farms, it had to be a joint activity. Men feared such independence would put women in a position to pay back their dowry and leave them.

The Women's Programme reviewed pilot villages in 1986 where graters had been installed. At least two of the original half dozen were removed as the original owners had lost control of the machine. In one village the chief had designated his son to be the sole operator who would hire out the machine to neighbouring villages.

2 Cooperative management of gari processing project Ghana

Summarized from:

"Technologies for Rural Women - Ghana", Technical Manual No. 4, ILO/National Council on Women and Development, Accra. January 1987.

Two pilot projects in Antoa and Damongo regions were initiated in northern Ghana under the guidance of the National Council on Women and Development (NCWD). Improved gari processing equipment consisting of a cassava grater, cassava press, gari roaster, and

a milling machine were installed. There were several reasons for locating the project at these sites. The proximity to Kumasi offered easy marketability. The area was already an important cassava producing region and thus offered employment for women engaged in the industry.

Both the NCWD regional representative and the village chief encouraged the women to organize themselves. The chief provided support by allocating land for a project site.

The original group consisted of 14 women and 1 man. All the women processed cassava into gari as a secondary occupation. Their primary activities included farming, selling cooked foods, clothes making and hiring out their labour to other farms.

Group members did not pay dues. They obtained the initial working capital from the Town Development Committee in order to purchase inputs such as sacks, metal basins, roasting pans and cassava. This loan has since been repaid.

Raw materials came from a variety of sources: purchased from other farms, harvested from group members' farms and the group-owned 10 acre farm.

The collection of firewood, harvesting, peeling, grating, roasting and bagging are done collectively as a group work effort. The gari is marketed in local villages and schools.

Group members have not shared the profits from sales amongst themselves but have chosen to use the funds to buy additional equipment. They feel they have benefitted from cooperative management in that they have received some of the product to supplement their families' diets. The group has expressed an interest in increasing their membership. Since many of the tasks require physical strength, they would like more men to join the group.

Several villagers had applied to join the group but the NCWD regional secretary insisted on limiting the number. Some disgruntled villagers complained that the cooperative had limited membership in order to be exclusive.

Clearly the members feel they have benefitted from pooling their labour resources. The husbands of the female members were happy about the project's existence in that they felt it reduced financial responsibilities at home.

3 Improved gari processing technologies - Nigeria

Summarized from:

C. E., Williams. "*The Effect of Technological Innovation among Rural Women in Nigeria: A Case Study of Gari Processing in Selected Villages of Bendel State, Nigeria*", Journal of Rural Development 5 (December 1982).

This case study relates to the introduction of improved gari processing technologies at an intermediate and industrial scale. In selected rural villages in Bendel State, where the processing and sale of gari is a predominant income source for women, the introduction of such technologies has had a profound effect on their income.

Traditionally, the ploughing, planting and weeding of cassava farms is done by men. There are few women who cultivate their own farms. More often, women buy the unharvested tubers from men and harvest the tubers themselves. The peeling and grating of cassava is done by hand. Gari pro-

cessing provides the main source of income for women in this area.

Diesel engine powered mechanical graters and hydraulic dewatering presses have replaced hand grating methods and reduced the time needed for pressing. The high purchase cost of these technologies has resulted in only men owning and operating these machines. All the men belonged to a union which fixed prices for operations and organised work schedules for members. These work schedules were determined by the number of machines available in any village and the length of market days. Such a system was intended to avoid conflicts and disagreements over indiviual economic gains.

The mechanical grater and press introduced at village level increased gari productivity. The time needed for grating, considered one of the most laborious steps in the process, was greatly reduced. The de-watering step, which normally took 5 - 8 days, was reduced to 1/2 an hour.

The introduction of the gari processing machinery also resulted in several adverse effects for the women in these areas. With the introduction of mechanical graters and presses, work traditionally done by women became the work of men. This transfer of control resulted in a transfer of income. Women lost an important income source. A set of four gari processing produced by a private Nigerian company were installed in one village in Bendel State. The system consisted of a cassava grater, dough sifter, mechanical press and garifier. Another component of the system, the peeler, was not bought.

The factory employed 48 workers to operate the machinery. Eleven of these were women whose tasks were to hand peel the cassava tubers and keep the factory clean. Gari produced from this factory was of very high quality and was only sold in the urban markets in places like Lagos and Ondo.

The sophisicated technology used by the factory was capable of producing very high quality gari. The garifier had a dual purpose of toasting as well as drying; heat supply could be regulated. The cylindrical machine fitted with prodders for stirring enabled the operator to avoid burns and eliminate contact with steam during stirring. It is interesting to note that the operations in the factory which were mechanised employed only male labour.

Female labour was minimal and was employed for a step in the process which was not mechanized.

Women were employed for this work because available peeling machines in Nigeria were seen to be ineffective and women's labour was less costly to employ.

From these experiences in Bendel State, the introduction of improved gari processing technologies were more beneficial to the men in the area than the women. At an intermediate level, the high capital cost of the machinery made it unavailable to the women while at the same time pushing them out of this economic activity altogether.

4 Transfer of Traditional Technologies - Papua, New Guinea

Summarized from:

Rashimah New. "*The Development of*

Sago Products in Papua New Guinea", Appropriate Technology Development Institute, Lae, Papua New Guinea, 1986.

Although sago is not a root crop, it plays a similar role to root crops in the diets of people in Papua New Guinea. Processed sago serves as an important starch-based carbohydrate.

The Appropriate Technology Development Institute undertook a sago product development programme in order to re-establish sago as a valuable resource, develop sago-based products and to assist small scale enterprises, at village level.

Traditional sago preparation methods were investigated in Papua New Guinea and in neighbouring countries. After research and testing, 'Sago Pops' were introduced to women's groups in the Sepik River Basin. 'Sago Pops' are a snack product made from sago slices which are first steamed, dried and finally fried in hot oil to produce a ready to eat food. This region was identified because sago was plentiful.

The women were initially reluctant to accept a sago product which was processed in a way they were unaccustomed to. After seeing that sago could be made into attractive products that could compete with imported foods, they became interested to learn these new processing techniques.

A year later it was found that 'Sago Pops' had become well known in the region and that several village-level enterprises had developed. This case study is cited in order to highlight the possibilities of transferring traditional processing technologies from one country to another. However, before pursuing such an approach, it is vital that local consumption habits and taste preferences be thoroughly investigated.

A Checklist of Questions to Ask when Planning a Root Crop Processing Project/Enterprise

The following questions should be asked by project planners and by decision makers before proceeding with the implementation of a root crop processing project.

Traditional Root Crop Processing

1. What is the extent of traditional and small-scale processing in the area?
2. What does the traditional process for a given product consist of?
3. Does the processing method vary in different areas?
4. If several processed products are made in your area, how do the methods differ? (in labour requirements, as seasonal activities, shelf-life of end-products, equipment used)
5. What is the place of women in traditional processing?
   a) are the processors farmers or landless?
   b) are there cultural taboos which prevent women from processing specific root crops and/or varieties?
   c) from cultivation to actual processing of the crop, what is the social organisation within the production cycle?
   (are specific steps done individually or collectively?, what steps do women or men dominate?)
6. Who owns the root crop?
   a) do the roles women and men play in the production cycle vary with ownership patterns?
   b) do landless women purchase root crops for processing and sale?
   c) is there more raw material available than can be processed in the traditional manner? If so, what is the constraint?
   (water/fuelwood/labour availability, capacity of equipment, credit availability, markets)
   d) are there seasonal shortages of the raw material?
7. Do the women cultivate and/or process the root crop principally for home con-

sumption or is it an important income source?

8. If the sale of processed root crop products are an income source, what proportion of the income do women earn and keep?
   a) what arrangements exist between women and men for sharing the proceeds of the production?
9. What is the traditional marketing mechanism and who controls it? (e.g. do women have access to markets?)
10. What are the major problems and constraints perceived by women processors?

Effects of Improved Technology on Traditional processing

Technical considerations

1. What is the estimated amount of production of the root crop?
2. What is the capacity of the improved technology — will it match the quantity of raw materials available to the processors?
3. Does the proposed technology address the major problems/constraints, within the various processing stages, perceived by women? (e.g. grating, pressing, grinding, milling)
4. Will the use of the improved technology reduce labour input as compared with the traditional method? How?
5. Will the equipment produce a greater quantity and/or better quality of products?
   (will the product have a different colour, taste or texture, - if so, will it be acceptable?)
6. Can the market absorb an increased supply of products?
7. What are the energy (sun, biomass, diesel, electricity) requirements of the equipment?
8. Will the users be able to meet those requirements on a regular basis?
9. Can the equipment be produced and/or maintained using local resources?
   a) are there capable local artisans or do they need to be trained?
   b) are the raw materials necessary for construction and workshop facilities available?
10. If parts need to be imported, will the users be able to afford the costs?
11. Will the users of the equipment need to be trained?
    a) is there already some familiarity with this type of technology?
    b) is training locally available?

SECTION 5

Socio-economic

1. What is the cost of the machine and related equipment?
2. Is the cost manageable on an individual or community basis?
   a) if on a community basis, does the traditional social organisation/culture of the producers operate on a collective basis?
   b) is this co-operation normally restricted to within family, tribal identity or other distinctions?
3. How are investment decisions in the community made? eg Individual, family, community, men only, elders only?
4. How long will it take to pay back the investment? What will the monthly profits be? Is the payback period and future net profits considered to be worth the present initial investment by the users?
5. If credit is needed is it accessible, and at what interest rate?
6. Will the women be able to repay the loan? (does seasonal production, labour availability etc. allow it?)
7. Who would control the use of the machine?
   a) Would it be village controlled or would individual men or women manage it on a lease basis?
   b) if village controlled, who would have access to it and on what terms?
   c) Who would be responsible for maintenance?
8. Considering traditional ownership patterns of land, possible gender domination of a given crop, and marketing control in your area, do you expect that the introduction of improved equipment will bring about any change in the pattern of work and distribution of benefits? If so, how?
   a) would root crop processing remain a significant income source for women after introduction of the machine?
   b) what proportion of the income would women earn?
   c) would work traditionally done by women be taken over by men if mechanised? Would this work displacement also mean loss of income?
   d) would the mechanisation of one stage create additional work (e.g. a need for pre-processing) and who is expected to do this work?
9. If the new technology brings scaling-up of production will the users be able to cope with the associated requirements of large-scale production such as handling finances, market and price negotiations, organising and managing personnel, acquiring regular supplies of raw materials?

SECTION 5

10. If the product is intended for markets beyond the local vicinity such as urban centres and neighbouring countries,
    a) will the quality be acceptable for these new consumers?
    b) can the product's normal shelf-life and packaging permit the demands of extended transport?

Rope bridge

From Wikipedia, the free encyclopedia

A **rope bridge** is a bridge constructed chiefly of rope. In its simplest form, it can be one or two ropes that bridge a river, enabling the traveller to be supported in their crossing and not be swept away. One rope above another, for feet and hands, may be referred to as a commando bridge.

More complicated rope bridges can involve the use of multiple ropes, and boards as footpaths. One of the most complex examples of a culture using these as permanent, rather than temporary crossings, is the Inca civilization.

An 1853 watercolor by Manuel María Paz shows two men crossing a rope bridge over the Igara Paraná River "made of wood and lianas".[1]

Rope bridge

A rope bridge in South America

Ancestor	None - this is a foundational type
Related	Inca rope bridge
Descendant	Simple suspension bridge
Carries	Pedestrians, livestock
Span range	short
Material	Grass or other rope, appropriate decking material
Movable	No

Rope-making list

Funem Habes? **Got Rope?**

Rope-making Step-by-step

Beginning to string up the yarn. Hold the end of the yarn with your thumb and bring it through the slot as shown. Take the yarn down to the jack and wrap it around the hook opposite the slot in the paddle.

The yarn will come back through the same slot and up and out the top center slot Again loop the yarn around the top center hook of the jack.

Bring the yarn back through the top center slot of the paddle down and out the final slot, out to the final hook and around the hook.

The rope jack should be strung up to look like this.

Bring the yarn from the third hook back through the third slot in the paddle and tie off. (If a thicker rope is wanted, simply go across the back through the 1st slot again and repeat the process with all three hooks and slots and then tie off).

To attach the swivel hook first put the two yarns from the top slot of the paddle into the hook, then bring the strands that are tied off onto the hook (the far right to far left slots)

Here we have a young 8 year old pulling back on the the swiveling hook as her 7 year old brother turns the handle on the jack. The strands are beginning to be formed.

When there is sufficient overtwist in the strands (when the strands are properly formed) you can begin to move the paddle forward. The swivel hook will start to turn, laying the rope up as you go. Make sure the person at the jack end continues revolving the hooks.

Remove the strands and place them on the top center hook in order (i.e. continue the direction of the twist with each strand) Once all three strands are on the top hook have the person at the jack turn the crank the opposite way while you hold the rope. Remove the free swiveling hook at the back end to make sure the rope tightens down on itself. This will set the rope.

The rope at the swivel hook end will not come unraveled, however it will unravel at the jack end. If you are doing a demonstration and making a couple hundred ropes a day you don't have time to do a crown and backsplice or whip the end of the rope. Insert a puller through all 3 strands as shown.

Insert a 6 to 8 inch piece of twine through the puller and draw it through the strands (A rug latch hook or crochet hook may also be used)

Tie the piece of twine using a square or surgeons knot and let the child who made the rope take it away.

Rope pump

From Wikipedia, the free encyclopedia

A **rope pump** is a kind of pump where a loose hanging rope is lowered down into a well and drawn up through a long pipe with the bottom immersed in water. On the rope, round disks or knots matching the diameter of the pipe are attached which pull the water to the surface. It is commonly used in developing countries for both community supply and self-supply and can be installed on boreholes or hand-dug wells.

Rigid valve rope pump

Description

A rope pump is a type of pump of which the main or most visible component is a continuous piece of rope, in which the rope is integral in raising water from a well. Rope pumps are often used in developing areas, the most common design of which uses PVC pipe and a rope with flexible or rigid valves. Rope pumps are cheap to build and easy to maintain. One design of rope pump using a solar-powered rope pump can pump 3,000 litres to 15 meters per day using an 80 watt solar panel .[1] Rope pumps can be powered by low speed gasoline/diesel engines, electricity,[2] human energy,[3] wind[4] and solar energy.[1]

Rope pump schematic

History

Chain or washer pumps were used by the Chinese over 1000 years ago.[5] In the 1980s Reinder van Tijen an inventor and grass roots activist, with the support of the *Royal Tropical Institute* of Amsterdam, created and began instructing various communities around the world how to make a rope pump from simple available parts using PVC pipes and plastic moldings. He began at Burkina Faso in Africa, continued to

Tunisia, Thailand and Gambia among others.[6] In Nicaragua, the technology was rapidly disseminated over the whole country and 25% of the rural population in Nicaragua now use rope pumps. It is also used in other parts of Central America with over 25,000 pumps installed to date.[5] In Africa the rope pump is now being used with solar energy.[1] By the end of 2009 more than 4 million people in 20 countries worldwide were using rope pumps for domestic and irrigation water.

Construction

The original rope pumps used knots along the rope length but can be made with flexible or rigid valves on the rope instead of knots. Alternatively they may use only rope, simply relying on the water clinging to the rope as it is quickly pulled to the surface.

Flexible valve rope pumps

Flexible valves can be made from cut pieces of bicycle wheel tubing. The valves are positioned approximately 20 cm apart on the rope. One disadvantage of flexible valve rope pumps is that they must be appropriately sized and thickness for different types, sizes and length of pipes.[7]

Rigid valve rope pump

Rigid valves using plastic or metal washers that fit tightly into the PVC pipe as the rope is dragged through are also used. If the fit is tight, the washers can be spaced up to half a meter apart. The deeper the well, the smaller the pipe inner diameter must be, given the available power constraints. These rope pumps are often worked with a hand crank[8]

Valves can also be made from knots in the rope itself.[9]

Valveless rope pumps

Valveless pumps rely on friction with water clinging to the rope, which is moved at high speed, often using a bicycle to produce the required speed. It is a less efficient design but is simpler to construct than the other rope pumps.[3]

Intellectual Property

Rope pump technology is in the public domain and there are no patents pending on it.[5]

Rope splicing

From Wikipedia, the free encyclopedia

Rope splicing in ropework is the forming of a semi-permanent joint between two ropes or two parts of the same rope by partly untwisting and then interweaving their strands. Splices can be used to form a stopper at the end of a line, to form a loop or an eye in a rope, or for joining two ropes together.[1] Splices are preferred to knotted rope, since while a knot typically reduces the strength by 20–40%,[2] a splice is capable of attaining a rope's full strength.[3] However, splicing usually results in a thickening of the line and, if subsequently removed, leaves a distortion of the rope. Most types of splices are used on 3-strand rope, but some can be done on 12-strand or greater single-braided rope, as well as most double braids.

Stages in splicing the end of a rope, from *Scientific American*, 1871

Contents

- 1 Types of splices
- 2 Splicing tools
- 3 See also
- 4 References
- 5 External links

Types of splices

- **back splice** (also called an **end splice**) – A splice where the strands of the end of the rope are spliced directly back into the end without forming a loop. It is used to finish off the end of the rope to keep it from fraying. The end of the rope with the splice is about twice the thickness of the rest of the rope. With nylon and other plastic materials, the back splice is often no longer used; the rope strands are simply fused together with heat to prevent fraying.[4]

Examples of splices in different stages of completion, from the *Nordisk familjebok*: a) long splice b) tapered short splice c) eye splice d) short splice

- **cut splice** (originally called **cunt splice**) – A splice similar to the eye splice. It is typically used for light lines (e.g., the log-line) where a single splice would tend to come undone, the rope being frequently wet.[5] It makes a very strong knot. A cut splice is a join between two ropes, made by side splicing the ends slightly apart, to make an eye in the joined rope which lies shut when the rope is taut. Its original name was bowdlerised to "cut splice".
- **eye splice** – A splice where the working end is spliced into the working part forming a loop.

- **ring splice** – Attached the working end of a rope to a ring or clew.[6]
- **chain splice** – Attached the working end of a rope to a chain.[7]
- **figure-eight "splice" knot**- A splice-like bend knot used for joining two ropes.
- **horseshoe splice** – A cut splice where the two sides of the loop are of unequal length.
- **long splice** – A **splice** used to join two rope ends forming one rope the length of the total of the two ropes. The long splice, unlike most splice types, results in a splice that is only very slightly thicker than the rope without the splice, but sacrifices some of the strength of the short splice. It does this by replacing two of the strands of each rope end with those from the other, and cutting off some of the extra strands that result. The long splice allows the spliced rope to still fit through the same pulleys, which is necessary in some applications.[8]
- **short splice** – Also a splice used to join the ends of two ropes, but the short splice is more similar to the technique used in other splices and results in the spliced part being about twice as thick as the non spliced part, and has greater strength than the long splice. The short splice retains more of the rope strength than any knots that join rope ends.[9]
- **Soft shackle** – Dyneema soft shackles are strong, light and safe and are increasingly replacing stainless steel shackles.

An unfinished cut splice

A line eye-spliced to a snap shackle.

A short splice, with ends whipped

[10]

Splices are often **tapered** to make the thicker splice blend into the rest of the line. There are two main types of tapering, the standard and the "West Coast Taper".

- **Standard tapers** progressively remove a portion of each remaining strand—one-third at a time is typical, resulting in a taper of two additional tucks beyond the splice—thus making each successive tuck produce a narrower splice. This is only practical with laid-lines, i.e., those made up of numerous strands laid side by side.
- **West Coast taper** (also known as a Fisherman's Taper) is effected by extra-tucks of entire strands, such that the second strand is interweaved one more time than the first and the third is interweaved an additional time after the second.

Splicing tools

A fid is a hand tool made from wood, plastic, or bone and is used in the process of working with rope. A variety of fid diameters are available depending on the size of rope being used. Styles of fid designs include:[11]

- **Swedish fid** is conical instrument with a somewhat long taper.
- **Tubular fid** aid in splicing double-braided rope.

- **Uni-fid** needed to splice braid with a parallel core.

A Marlinspike is a tool, usually made of steel and often part of a sailor's pocketknife, which is used to separate strands of rope from one another. They can range in size anywhere from 3 inches to 5 feet long, with a round or flattened point.[12]

A pulling fid is often used for smaller diameters of braided ropes. Also a Softfid is a great tool when dealing with tightly braided ropes.

Book:	Toolcare
Chapter:	7 Miscellaneous repairs
Section:	Ropes
Meta Data:	Details

Ropes used for tree work should be kept separate from ropes used for general work, which may include pond work, hauling wheelbarrows, towing vehicles and so on. Ropes can be distinguished by marking them with fabric dye. Mix up a quantity of cold water dye, suitable for the type of rope, and dip a section of rope into it.

Natural-fibre ropes are still available made of sisal or manila (hemp), but are generally less strong and more liable to rot than man-made fibre ropes. Ropes of man-made fibre are, in order of strength, made of nylon, polyester (Terylene) or polypropylene (see table below).

According to the way they are made, ropes are either hawser-laid (cabled) or kernmantel. Hawser-laid ropes have fibres twisted together to make strands, and then three strands twisted together to make the rope. They can easily kink and require careful coiling. Kernmantel ropes, made of polyester, have a large number of filaments running straight down the rope, encased in a braided sheath. They have a high tensile strength and are non-kinking. Kernmantel ropes for tree work have low stretch. Kernmantel ropes designed for rock climbing have very high stretch and should never be used for tree work.

Hawser-laid polypropylene ropes are the type most commonly used for conservation work. Although these do not rot in water, they should still be stored dry and away from chemicals and batteries. Polypropylene ropes float, which is an advantage for pond work. Hawser-laid sisal or manila ropes will rot if kept damp.

If ropes are returned to the store very muddy, they should be washed, coiled loosely to dry and then coiled for storage. All ropes should be checked once a month for damage and wear by uncoiling them and making a careful visual check.

Very badly frayed or damaged ropes should be discarded. Ropes with one or more points of damage can be cut and the sound lengths kept for general purposes. Singe the ends of man-made fibre ropes to seal them. Use fine string (whipping twine) to whip the ends of natural-fibre ropes, as shown above.

The table below gives the breaking load and safe working load of various sizes and types of rope.

Rope (diam.)	Breaking load (kg)	Safe working load	
Sisal	8mm	480	80
Sisal	12mm	950	158

Sisal	16mm	1780	296
Sisal	24mm	4060	676
Manila	8mm	540	90
Manila	12mm	1070	178
Manila	16mm	2030	338
Manila	24mm	4570	761
Polypropylene	8mm	960	160
Polypropylene	12mm	2030	383
Polypropylene	16mm	3500	583
Polypropylene	24mm	7600	1266
Polyester	12mm	3000	500
Nylon	10mm	2080	346
Nylon	12mm	3000	500
Nylon	14mm	4100	683

Rope water pumps

Lift Disk Pump

This type of pump uses flat disks (shown on edge in red here) attached to a chain or rope. The disks draw water up a tube.

This type of pump is probably thousands of years old. It is similar to a Rag Pump or Bucket Pump.

(This is a still representation and possibly also a low-resolution image of a pump which is fully animated in the CD-ROM version of this glossary.)

http://www.animatedsoftware.com/pumpglos/liftdisk.htm

Rag Pump

Rag Pumps have been used for at least 400 years and probably a lot longer.

Their use was widespread. Rag pumps were used aboard large sailing ships to bring salt water up for various uses and they were also used in wells. Horses, a water wheel, or "tramping men" all might have supplied the power to turn the wheel.

Cloth bundles, usually just rags, are tied in knots at intervals on a rope or chain. The chain is then hung around a wheel and through a tube that goes below water level. The base of the tube is flanged to prevent the rag balls from catching.

When the wheel rotates water is drawn up a tube.

This pump is very similar to a Lift Disk Pump and Bucket Pump.

(This is a still representation and possibly also a low-resolution image of a pump which is fully animated in the CD-ROM version of this glossary.)

Bucket Pump

The Bucket Pump is similar to the Rag Pump and Lift Disk Pump but does not require a tube to draw the water up. It is not very common anymore, but can still be found occasionally.

One advantage of this pump is that the buckets don't turn upright until they are well below the surface of the water. They fill with clean water, and bring up less of the scum that often floats on the surface of a well.

Large old sailing ships sometimes used Bucket Pumps. They were also used on farms and many other places.

Of course, the length of the chain and the number of buckets can vary greatly.

(This is a still representation and possibly also a low-resolution image of a fully animated pump.)

http://www.animatedsoftware.com/pumpglos/pumpglos.htm

Rope Water pump!
Made simpler every time you make one.

The WOT Rope pump with plastic discs in action.

Above a detail of the rope-pump, allowing a very low-cost installation for lifting water by hand or mechanical drive. Main advantage of the rope-pump is the continuous pumping action so minimal force is needed to lift water. When applying mechanical drive, the continuous force is also optimal, in contrast to most valve-pumps. (The constant force results in less wear and higher efficiency) I will add better pictures soon, to show how to assemble the pump parts easily.
Most critical part of the pump is the bottom turning-point of the rope. The wear can be minimised by use of a ceramic or glass cilinder (small bottle or jar) and the disks should enter the lifting tube easily by flanging (widening) the bottom end. Shown on the photos are two plastic/rubber fixtures of the PVC tubes, one already fixed into concrete. The thicker tube is used to guide the rope downward, the thinner one lifts water if the disks fit neatly inside. Note that one broken disk will not harm the pumping action, because a next disk will still lift the water. The number of disks is not critical, at least three are necessary but then the fit is very critical. More optimal is around 10 disks, also depending on the distance to lift the water. The disks should be at least half a meter apart.
At the top of the lifting tube, a widening and a T-joint are required to allow the water to be delivered smoothly. The rope can be driven by hand from a "wheel" which can be made from an old car type and four pieces of wood.
Cut the sides of the car tyre, resulting in circles approx 5 cm wide. Join the two sides by bolts & nuts or by driving nails through the two sides, approx 1 cm from the inner side.

The part of the nails sticking out can be bent to lock the two tyre sides together in a circular V-shape. The rope can be run through the bottom of the V, where it is caught, so the pulling force of a spinning wheel will result in the rope being pulled through the tube, it should not result in the rope slipping between the tyres. The V-wheel can be caught on the middle of four pieces of wood as shown on the last photo. No attachment is needed, except a tight fit. The pieces of wood are screwed on a square axis, which can turn by locally (at two places) rounding it. These parts are caught between two metal slabs at the top of two poles. One slab is bent and entered into a hole of the pole, made with a saw. The second slab is put on top of the first slab and the wooden axis laying in the first slab. Recently we made a bore-hole of only 8 cm (3 inches) wide, 7 meters deep and fitted a rope-pump on top. (Photos follow shortly) Ordinary nylon rope can be used, but regular maintenance/replacement is needed when the rope shows wear due to frequent use. Disks can be made from rubber (the inner tube of a tyre or from the soft side of the outer tyre) but can also be made from plastic. We (the WOT) are developing a machine to automate the production of plastic discs. One of them is shown on the first photo.

My notes – use a stationary bicycle mounted on supports to use the back wheel to drive a rope pump. Use rubber balls pushed onto rope with wire seat cover staples or coat hanger wire to hold on to the rope from slipping.

The WOT rope pump explained

The bottom picture shows the wheel, the axis and the top of the delivery tube. The working principle and the construction is explained to development workers, who actually are assembling and erecting a pump during our yearly training week.

Shopping List:
Follows shortly....

ARTICLE OF THE MONTH

Each month there will be a new knot related article displayed on this page.

THIS MONTH'S IS THE :

<

ALAMAR KNOT

The alamar knot is a decorative knot related to the pretzel knot. The pretzel knot is tied in a single strand; the alamar knot is tied by doubling the strands as showwn in [Step 1]

[Step 1] Double the strand as shown.

[Sterp 2]

[Sterp3]

[Step 4]

[Step 5] Add tassels or other end decorations.

KNOTBOARD OF THE MONTH

TURK'S HEAD:

Description ----

Three strand braid worked in a continuous circle.

Use ----

(1) As a decorative knot around a staff or railing.
(2) Worked tight around a checked or cracked tool handle or canoe paddle to reinforce them.
(3) As a neckerchief slide or wogal.

Comments ----

The form of Turks head shown here is a five crown Turk's head, this is only one of a group of knots that go by the name Turk's heads. The crown number is determined by counting the number of bights at the edge of the knot. To make a larger loop the, increase the size of the wraps made in steps 1 - 4 and then, at step 7 use three strand braiding to increase the number of crowns. The number of crowns can be increased by increments of three; so that the number of crowns in a larger loop can be 8, 11, 14, etc..The size of the finished Turk's head depends on the size of the rope used and the number of times the strand is chased.

Other Names ----

Three lead by five bight Turk's head, ordinary Turk's head.

Narration ------ (For Turk's head knotboard.)

(1) Start at the center of the line, by taking a

bight around an object (the fingers of the left hand work well) (2) Complete the round turn and cross the running end over the standing end. (3) Take a second bight around the object so that the running end is between the standing end and the first wrap. (4) Lay the running end across the first wrap then (5) tuck the running end under the standing end. (6) lay the standing end across the second wrap and (7) tuck it under the first wrap. (8) rotate the knot around the object so that you are looking at the opposite side. (9) Cross the second wrap over the first wrap. (10) Reeve the standing end through the eye formed between the two wraps. (11) Reeve the running end through the eye between the two wraps so that the ends are in opposite directions. (12) Chase, follow, the strand of the knot two or three times. Cut off and secure the ends.

[NOTE] To determine the length of line to use, wrap the line around the object four times for a single strand knot. Add three and one half wraps for each time you intend to chase the original strand.

KNOTBOARD OF THE MONTH

RINGBOLT HITCHING:

Description ----

A series of interlocking lark's head knot that form a ridge around the outside of a ring or loop.

Use ----

To prevent chafing; as a decoration.

Comments ----

There are many forms of ringbolt hitching, the form shown here is one of the simplest and does not require the use of a needle as many other forms do. Ringbolt hitching was used to prevent chafing of ropes that were reeved through hand forged iron rings and to keep them from clanging against objects around them. In the present,

ringbolt hitching can be used to protect synthetic ropes that are easily chafed by a applying a layer of material that is not easily chafed.

Other Names ----

Platted Ring; Hog Backing; Cockscombing.

Narration ------ (For Ringbolt Hitching knotboard.)

(1) Start the ringbolt hitching by tying a half knot around the object. (2) Tie a half hitch around the object so that the standing end is trapped under the half hitch. (3) pull the half hitch tight. (4) Tie the next half hitch in the opposite direction around the object. (5) Pull the half hitch tight. (6) Tie another half hitch in the opposite direction around the object; the same direction as the first half hitch. (7) Pull half hitch tight. (8) When the length of the ringbolt hitching is within 5 or 6 half hitches of being long enough; form a bight in the a short piece of twine so that the eye of the bight is toward the end of the work. (9) Continue to add half hitches until the ringbolt hitching is completed; reeve the running end through the eye of the bight. (10) Use the short piece of twine to pull the running end under the half hitches. (11) Cut off the end of the twine.

KNOTBOARD OF THE MONTH

BOATSWAIN'S WHISTLE KNOT:

Description ----

A two lead knot that is built up from two interlocking underhand loops to looks like a turk's head knot when it is worked tight.

Use ----

As a decorative knot to attach a whistle or a knife to a lanyard ---- to form a toggle or button.

Other names ----

Sailor's knife lanyard knot, marlingspike lanyard knot, single-strand diamond knot, two strand diamond knot ---- pipe lanyard knot.

Narration -- (For

Boatswain's Whistle Knot knotboard.)

((1) Use the left hand to hold the middle of a strand of rope so that the loop of the bight is to the back of the hand and the two leads are between the fingers and hanging down across the palm. (2) Use the bottom lead, to lay an underhand loop over the standing end of top lead. (3) Form a bight in the bottom lead so that its running end is under the running end of the top lead. (4) Weave the running end of the bottom lead over the right edge of the top underhand loop, then under the standing end of the bottom lead, and over the left edge of the top underhand

hand loop. This forms two interlocking underhand loops. (5) Form the next bight by placing the running end of the top lead under the top edge of the top underhand loop. (6) Reeve the running end of the top lead to the outside of the standing end of the bottom lead and up through the middle of the interlocking underhand knots. (7) Form the next bight by placing the running end of the bottom lead under the bottom edge of the bottom underhand loop. (8) Reeve the running end of bottom lead to the outside of the standing end of the bottom lead and up through the middle of the interlocking underhand knots. (9) Work the knot tight.

ROPE WORKS ©1996 Gerald L. Findley, all rights reserved

KNOTBOARD OF THE MONTH

DIAGONAL LASHING:

Use ----

Diagonal lashing is used to bind poles together that cross each other but do not touch when their ends are lashed in place in a structure.

Comments ----

The diagonal lashing gets its name from the fact that the wrapping turns cross the poles diagonally.

The diagonal lashing can be used to bind poles that cross each other from 90o to 45o. If the angle between the poles is less than 45o a shear lashing should be used.

The diagonal lashing makes use of the timber hitch to pull poles together that are not touching each other. The timber hitch allows the poles to be drawn together without changing the relative positions of the poles. [NOTE] If a square lashing were used to bind poles that do not touch, the beginning clove hitch would pull the cross pole toward the clove hitch causing unnecessary bowing of the cross pole and could also produce a force that would act along the length of the pole to which the clove hitch is tied. These additional force, if strong enough, can place unnecessary strain on other lashing within the structure causing the structure to twist and fail.

Narration ------ (For Diagonal Lash knotboard.)

(1) Tie a timber hitch diagonally around both poles. (2) Start the wrapping turns on the opposite diagonal to the timber hitch, by pulling the rope tight so that the poles contact each other. (3) Take 3 to 4 wrapping turns; keep

the wrapping turns parallel; pull each wrapping turn tight. [NOTE] If the wrapping turns are allowed to cross, the increased friction between the strands of the rope will make it difficult to tighten the wrapping turns. (4) Start the second set of wrapping turns by going past and around the vertical pole. [NOTE] Going around the pole the rope allows the direction of the rope to be changed without crossing the first set of wrapping diagonally. (5) Take 3 to 4 wrapping turns; be sure to keep the wrapping turns parallel; pull each wrapping turn tight. (6) Start the frapping turns by going past and around one of the poles. [NOTE] Going around the pole with the rope allows the direction of the rope to be changed without crossing the wrapping turns diagonally. (7) Take 2 to 3 frapping turns; keep the frapping turns parallel. Be sure to pull each turn tight. (8) End the lashing with a clove hitch. Take the first half hitch of the clove hitch by going past and then around one of the poles. Lock the half hitch tight against the lashing by working it tight. (9) Take a second half hitch around the pole. (10) Work the second half hitch tight against the first half hitch so that the clove hitch is locked against the lashing.

[NOTE]

If very smooth rope is used, the lashing can be made more secure by adding a third or forth half hitch to the clove hitch.

ROPE WORKS ©1996 Gerald L. Findley, all rights reserved

KNOTBOARD OF THE MONTH

Each month there will be new knotboard and descritive text displayed on this page.

THIS MONTH'S IS THE :

CONSTRICTOR KNOT:

Dscription ----

A clove hitch with a half knot under the cross-point.

Use ----

To tie a smaller rope to a larger one, or to tie a rope to a stake or pole; a substitute for whipping; as a lashing for light construction ; as a hose clamp.

Comments ----

A secure nonslip knot ; difficult to untie without cutting.

[NOTE]

Use this method of tying the constrictor knot on either side of where you intend to cut a rope. This is a fast and easy way to prevent a rope from unlaying when it is cut.

Narration ------ (For Constrictor Knot knotboard.)

((1) take a bight around an pole. (2) Continue wrapping the running part around the pole so that the running part crosses over the standing part. (3)

Complete the turn around the pole. (4) Cross the running part over the standing part so that (5) a bight is formed around the standing part. (6) Reeve the running part under the cross part of the loop in the standing part to form a half knot under the cross-point. (7) Pull the standing tight. (8) Lock the knot tight by pulling hard on both the standing part and the running part.

KNOTBOARD OF THE MONTH

MONKIE'S PAW:

Dscription ----

Two forms of the monkey's paw are sown here the first is formed from four interlocking loops: a four crown turk's head; the second is constructed from three interlocking coils.

Use ----

The core determines what the monkey's paw can be used for. When tied over a stone or heavy ball, the monkey's paw can be used to add weight to a heaving line. If tied over a cork ball with small cord the monkey's paw makes a good float for boat keys or other small items used around a water front. Tied over a ball of twine or other soft material, the monkey's paw can be used as weight on the end of a rope for the game jump the shot. A Monkey's Paw can also be used as a toggle..

Comments ----

Neither form of the Monkey's Paw has an advantage over the other. Which one you choose to use is a matter of personal preference.

Core Size -----

The diameter of the core should be between three and four diameters of the rope being used..

Narration ------ (For Monkey's Paw Turk's Head knotboard.)

(1) Form an overhand loop (2) Form a second

overhand loop over the left edge of the first overhand loop . (3) Cross the standing end over the running end. (4) Weave the running end across the loops by placing the running end over the right side of the top loop (5) then under the right side of the bottom loop (6) next, over the left side of the top loop (7) and finally under the left side of the of the bottom loop. (8) Pull the running end through until a third loop equal in size to the first two loops. (9) Add the fourth loop by placing the running end parallel to the standing end. (10) Chase the original pattern 2 to 3 times. (11) Work tight over the core.

ARCHIVE

KNOTBOARD OF THE MONTH

Each month there will be new knotboard and descritive text displayed on this page.

THIS MONTH'S IS THE :

MOORING HITCH:

Dscription ----

An underhand loop toggled to the standing part with a bight made in the running end.

Use ----

To securely tie off a rope so that it can be quickly untied, especially a small boat to a dock or piling.

Comments ----

A secure knot that is easily tied or untied in wet or dry rope; when properly tied a non closing loop is formed, this allows the hitch to move up or down a piling as the water level changes.

Narration ------ (For Mooring Hitch Knotboard.)

(1) Take a bight around an object. (2) Form an underhand loop in the running part. (3) Place the eye of the underhand loop over the standing part. (4) Pull a bight of the standing part through the eye of the underhand loop. (5) Pull the underhand loop tight around the bight. (6) Place the running part under the eye of the bight that was pulled through the underhand loop. (7) Pull a bight of the running part through the eye of the standing part bight. (8) Pull on

the standing part to tighten the standing part bight around the running part bight.

KNOTBOARD OF THE MONTH

Each month there will be new knotboard and descritive text displayed on this page.

THIS MONTH'S IS THE :

JUG KNOT:

Use ----

- to provide a convenient carrying handle for jug or bottle ---- to attach a tool, such as a hammer to a security line to prevent accidental dropping --- to add a wrist loop to a walking staff --- to attach a safety line to a canoe paddle ..... use your imagination, but be sure that you keep safety in mind.

Other Names ----

Jar knot, moonshiner's knot, hackamore, bridle knot..

Comments ----

The most common use is to provide a loop handle attached to the neck of a bottle. The loop handle makes it easy to carry several bottles with one hand. If a toggle or a two strand button knot such as boatswain whistle knot is added to the free end of the rope, The loop of the jug knot can be use to toggle the bottle to a belt so that the bottle can be use as a canteen.

Plastic bottles with screw-on lids such as soda, sport drink, and mineral water bottles make strong,

lightweight containers for carrying water on hikes and camp outs. 2 and 3 liter soda bottles are large enough to use as water containers around the camp kitchen. Smaller bottles (8 to 16 oz.) can be used as personal water bottles or canteens. These bottles can be made even more convenient by using a jug knot to attach a loop handle.

To help keep your water cool and refreshing in hot weather, place a sock over the bottle, wet the sock when you fill the bottle, evaporation will do the rest.

In cold weather, carry your water bottle under your coat. A dry sock placed over the bottle will help keep the water from freezing. In cold weather, carry your water bottle under your coat. A dry sock placed over the bottle will help keep the water from freezing.

In cold weather, carry your water bottle under your coat. A dry sock placed over the bottle will help keep the water from freezing.

Narration ------ (For Jug Knot Knotboard.)

Narrative ---- (For jug knot knotboard) (1) Form a bight in the middle of a 24 to 30 inch long by 3/16 inch diameter rope. (2) Fold the bight down over the standing ends to form two loops. (3) Place the right loop over the side of the left loop. (4) Weave the middle of the bight under the standing end; then over the left edge of the right loop; (6) next go under the right edge of the left loop; (7) finally pass the bight over the right side of the left loop. (8) Turn the tops of the original loops down over the knot. (9) Place the knot over the neck of a bottle and work the knot tight so that the bight forms a 4 to 5 inch loop handle and the loose ends are even.

KNOTBOARD OF THE MONTH

Each month there will be new knotboard and descritive text displayed on this page.

THIS MONTH'S IS THE :

BELAYING TO A CLEAT:

Use ----

To secure a flag lanyard, to moor a boat to a dock.

Comments ----

Belaying to a cleat is a fast non-jamming method of securing a rope anywhere along its length without reeving any part of the rope through or around anything.

Narration ------ (For Belaying to a CleatKnotboard.)

(1) Take a turn around the cleat and pull the line tight. (2) Complete a round turn around the cleat . (3) Place the line across the cleat. (4) Take a bight around one horn of the cleat. (5) Place the line across the cleat a second time. (6) Take a bight around the other horn of the cleat to form a figure eight around the horns of the cleat. (7) Repeat steps 3 through 6. (8) Form an underhand loop. (9) Place the eye of the underhand loop over the horn of the cleat. (10) Pull the underhand loop tight to form a half hitch around the horn of the cleat, this locks the rope in place.

KNOTBOARD OF THE MONTH

Each month there will be new knotboard and descritive text displayed on this page.

THIS MONTH'S IS THE :

WHIPPING:

Description ----

Twine wrapped and secured to the end of a rope.

Use ----

To prevent the fraying of the end of a rope.

Comments ----

Even though "whipping" is done in several different ways, the finished "whippings" have similar appearance: the ends are secured under the turns, the length of the whipping is equal to the diameter of the rope, and all turns are parallel. Synthetic rope, rope made of plastic, should be whipped and fused to prevent the rope from fraying. Fusing helps to hold the whipping in place and the whipping helps to prevent the fused rope strands from braking apart.

Narration ------ (For Whipping Knotboard.)

(1) Take a turn around the cleat and pull the line tight. (2) Complete a round turn around the cleat . (3) Place the line across the cleat. (4) Take a bight around one horn of the cleat. (5) Place the line across the cleat a second time. (6) Take a bight around the other horn of the cleat to form a figure eight around

the horns of the cleat. (7) Repeat steps 3 through 6. (8) Form an underhand loop. (9) Place the eye of the underhand loop over the horn of the cleat. (10) Pull the underhand loop tight to form a half hitch around the horn of the cleat, this locks the rope in place.

KNOTBOARD OF THE MONTH

Each month there will be new knotboard and descritive text displayed on this page.

THIS MONTH'S IS THE :

FIGURE-EIGHT KNOT:

Description ----

Interlocking overhand loops, the running part goes through the eye of one loop and the standing part goes through the eye of the other loop.

Use ----

(1) As a stopper knot; to keep a rope from unreeving from a pulley block; to prevent a rope from unlaying. (2) When tied on a bight, makes a reliable loop for rescue work and mountaineering.

Comments ----

Easier to tie and untie than an overhand knot; does not damage the rope fiber or jam like an overhand knot.

Narration ------ (For Figure-eight Knotboard.)

(1) Form an overhand loop. (2) Take a bight around the standing part. (3) Form the second overhand loop by bring the running part over the top edge of the firs overhand loop. (4) Complete the knot by reeving the running part through the eye of the first overhand loop (5) and pull tight.

FIGURE-EIGHT ON A BIGHT:

Description ----

Interlocking overhand loops tied on a bight in the running part (the bight is used as the running part); the running part goes through the eye of one loop and the standing part goes through the eye of the other loop.

Use ----

(1) Makes a reliable loop for rescue work and mountaineering. (2) As a stopper knot; to keep a rope from unreeving from a pulley block; to prevent a rope from unlaying.

Comments ----

Easier to tie and untie than an overhand knot; does not damage the rope fiber or jam like an overhand knot on a bight.

Narration ------ (For Figure-eight on a Bight Knotboard.)

(1) Form a bight in the rope. [NOTE] Treat the two strands of the bight as a single strand as the rest of the knot is tied. (2) Form an overhand loop. (3) Take a bight around the standing part. (4) Form the second overhand loop by bring the running part over the top edge of the firs overhand loop. (5) Complete the knot by reeving the running part through the eye of the first overhand loop (6) and pull tight.

KNOTBOARD OF THE MONTH

Each month there will be new knotboard and descritive text displayed on this page.

THIS MONTH'S IS THE :

TRIPOD LASHING:

Description ----

A shear lashing around 3 poles.

Use ----

To bind three poles together, for the construction of a tripod. ---- To bind three poles together that contact at the same point in a structure

Comments ----

The tripod lashing is a shear lashing that binds three poles together at the same point. ---- The tripod lashing gets it name from the fact that its most common use is the construction of a tripod. ----The tripod lashing can be used just about any where in a structure that three poles cross each other at the same point and the same time in the sequence of construction. ---- Tripod lashing takes two main forms; with racked wrapping turns (the rope is woven between the poles) and with plain wrapping turns (the rope is wrapped around the poles without weaving the rope between the poles). When the lashing is made with racking turns the rope contacts each pole around its entire circumference ; this

contact makes the tripod lashing with racking turns the most secure form of tripod lashing: therefore tripod lashing with racking turns should be used when safety is important. However, for light structures where there would be no danger if the lashing slipped, the faster to tie tripod lashing with plain wrapping turns may be used.

Laying Out The Poles ----

For most tripod lashings, lay the pole side by side with the butt ends aligned. The alignment of the butts of the pole insures that the tripod legs are the desired length.

[NOTE]

The practice of laying the center pole in the opposite direction to the outside poles creates several problems. When the poles are laid in opposite directions the wrappings must be put on loosely so that when the center pole is rotated to its proper position the lashing is tightened around the poles. If the wrappings are put on to tight, the rope is stretched causing damage to the rope fibers, therefore weakening the lashing. On the other hand, if the rope is wrapped two loosely, the lashing will not tighten enough when the center pole is rotated and the lashing will be able to slip along the length of the pole. Either way, the rope to loose or the rope to tight, a dangerous situation is created.

Setting Up A Tripod -----

Set up the tripod by crossing the outside poles so that the cross point of the poles is under the center pole. Crossing the outside poles under the center pole causes part of the load that is placed on the tripod to be taken up by the wood to wood contact of the poles.

Narration ------ (For Tripod Lashing Knotboard.)

(1) Tie a clove hitch around one of the outside poles. (2) Secure the standing part by wrapping it around the running part. [NOTE] Wrapping the standing part around the running part prevents the clove hitch from slipping around the pole. If the clove hitch slips the lashing will loosen up from the inside. (3) Start the racked wrapping turns by weaving the rope between the poles. (4) Take a total of 5 to 7 wrapping turns. Pull each wrapping turn tight as it is made. [NOTE] The stiffness of the tripod lashing depends on the number and tightness of the wrapping turns. As the tightness of the wrapping turns or the number of wrapping turns increases, the stiffness of the tripod will increase. (5) Take the first frapping turn by taking the rope around the pole that the clove hitch was tied to, then between the outside pole and the center pole. (6) Take 3 frapping turns. Pull each frapping turn tight as it is made. (7) Start the second set of frapping turns by taking the rope across the center pole and reeving it between the second outside pole and the center pole. Take the second set of frapping turns in the opposite direction to the first set of frapping turns. [NOTE] Taking the second set of frapping turns in the opposite direction to the first set of frapping turns prevents the rope from crossing the wrappings at a diagonal. Unnecessary crossing of the rope increases friction between the strands of the rope making it difficult to tighten the lashing properly. (8) Take a total of 3 frapping turns. Pull each turn tight. (9) Take the first half hitch of the ending clove hitch around the second outside pole by taking the rope past the pole and then around the pole. (10) Work the half hitch tight so that it is locked against the lashing. [NOTE] See the narration for square lashing for instructions on working the half hitch tight. (11) Take the second half hitch of the ending clove hitch. (12) Work the half hitch tight to complete the ending clove hitch. [NOTE] If the clove hitch is not worked tight so that it is locked against the lashing the clove hitch will slip around the pole allowing the lashing to loosen. [NOTE] If very smooth rope is being used, a 3rd half hitch should be added to the clove hitch to insure that the lashing will stay in place.

KNOTBOARD OF THE MONTH

Each month there will be new knotboard and descritive text displayed on this page.

THIS MONTH'S IS THE :

SHEET BEND:

Description ----

An interlocked bight and half hitch.

Use ----

To temporarily join two ropes, especially if the ropes are of different sizes.

Comments ----

The sheet bend is a secure but easily untied knot. ---- When tying the sheet bend the running parts should be left long because there is some initial slip in the knot when the knot is first brought under tension. ---- The proper and more secure way to tie the sheet bend is so that the two end the rope are on the same side of the knot.

Other Names ----

Weavers knot

Related Knots ----

Bowline; becket hitch; these knots share the same form but are tied in a different way or have a different use.

Narrative ---- (For sheet bend knotboard.)

(1) Form a bight in the running part of the

left-hand rope. (2) Reeve the running part of the right-hand rope through the eye of the bight in the left-hand rope. (3) With the right-hand running part take a bight around the running part and the standing part of the left-hand rope. (4) Pass the right-hand running part over the left-hand standing part, (5) under the right-hand rope, and (6) over the standing part of the left-hand rope. (7) Pull tight.

KNOTBOARD OF THE MONTH

Each month there will be new knotboard and descritive text displayed on this page.

THIS MONTH'S IS THE :

MASTHEAD KNOT:

Description ----

A multiple loop knot formed by reeving the loosely made loops of two over hand knots through each other and then securing the knot to a mast (pole).

Use ----

On board ship, a masthead knot was used to rig a temporary mast if the mast was lost in battle or during a storm. On land a masthead knot can be used to rig a gin pole or a flag pole.

Comments ----

There are several forms of the Masthead Knot. This form of the Masthead Knot was chosen for its symmetry and the ease of transition to the running half hitches used to secure it to the pole.

Other Names ----

Jury mast knot, pitcher knot.

Narrative ---- (For masthead knot knotboard.)

(1) Loosely tie two over hand knots. (2) Place the loop of one overhand knot on top of the loop of the loop of the other over hand knot. (3&4) Reeve the

loops of the overhand knot through the half knot part of the opposite overhand knot. (5) Place over a pole and draw the three loops up even. (6) Secure to the pole with a series of running half hitches above and below the mast head knot.

[NOTE]

A forth loop my be formed by tying or splicing the ends together. If a fourth loop is made, nail a cleats to the pole to prevent the mast head knot from slipping.

[NOTE]

Attach the guy lines to the loops with becket hitches.

KNOTBOARD OF THE MONTH

Each month there will be new knotboard and descritive text displayed on this page.

THIS MONTH'S IS THE :

FLOOR LASHING:

Use ----

to lash a series of poles to a set of stringers to form a flat surface such as a deck, a table top, or a road way.

Comments ----

When using a floor lashing, both ends of the decking poles must be lashed at the same tine to insure a firm even surface.

When placing the decking poles on the stringers, lay the decking poles so that their butt end are in alternating direction. Alternating the but ends of the decking poles will compensate for the natural taper of the poles so that the length of the decking along each stringer will be equal.

Narrative ---- (For floor lashing knotboard)

(1) Tie a clove hitch around each stringer. (2) Secure the short end of the rope by wrapping it around the running end (wrap with the lay of the rope). (3) Place the decking poles on the stringers and take a bight around the first pole. (4) Next, on the inside of the stringer, pull a bight up between the first decking pole and the next decking pole. (5) Place the eye of

the bight over the end of the decking pole. (6) Pull tight. (7) On the outside of the stringer, place a bight over the next decking pole. (8) Pull tight. (9) Repeat steps 4 through 8 until all decking poles are lashed in place. (10) Tie the first half hitch of the ending clove hitch. Work half hitch tight. (11) Tie the second half hitch of the ending clove hitch. Work half hitch tight (12) to form clove hitch.

ARTICLE OF THE MONTH

Each month there will be article on this page.

THIS MONTH'S IS THE :

MAULS:

A maul is a wooden club or hammer that is used for driving stakes or wedges and for safety reasons should be used instead of an ax.
Using an ax instead of a maul exposes the user to the danger of being cut by its sharp edge. Even if the edge is covered by a sheath, a glancing blow can cause the sheath to be ripped off or to be cut through.
The pole of an ax serves as a counterweight to the blade. This counterweight adds to the balance of the ax head and helps to control and increase the force of momentum delivered to the bit. The ax head is shaped in such a way that the momentum of the ax head is delivered through the thin walls of the eye. However, when an ax is being used as a hammer, this same shape causes the eye of the ax head to spread and the handle to loosen.
The flat surface and angular edges of an ax pole makes it difficult to strike a stake squarely. This difficulty in striking a square blow results in most blows delivering some there force sideways, causing the end of the wooden stake to flare and split very quickly. In addition, when the pole of an ax contacts a stake, the metal surface of the pole lacks the ability absorb any of the force of the impact this contributes to the destruction of the stake. A wooden maul, on the other hand, absorbs some of the impact of the initial contact and a maul has no angular edges. Therefore, more of the force of the maul is used to do useful work and less of the force is used up in deforming or splitting the stake.

ARTICLE OF THE MONTH

Each month there will be an article on this page.

THIS MONTH'S IS THE :

FUSIING:

Use ----

To prevent a rope from fraying.

Comments ----

The ends of a synthetic rope can be fused to prevent the rope from fraying. This is done by heating the end of the rope so that the ends of the rope fibers melt together.

The fusing can be done by holding the end of the rope to the side of a candle or other small flame. If the end of the rope is placed in the flame or held too close to the flame, the plastic will ignite causing the end of the rope to turn black. Burning plastic can also give off toxic fumes . If the end of the rope is held above the flame, unburned carbon particle will be deposited on the melted plastic causing it to turn black. A candle flame will generate enough heat to fuse the end of a rope up to about one inch in diameter. If the rope is larger than one inch, a propane torch will work better .

ARTICLE OF THE MONTH

Each month there will be new knotboard and descritive text displayed on this page.

THIS MONTH'S IS THE :

SPANISH WINDLESS:

Description ----

A Spanish windless is a device for moving heavy loads such as rocks and logs.

[WARNING]

When setting up a Spanish Windless do not use nylon or other synthetic fiber ropes that stretch under a load. If you slip or let go of the poles the energy you used to stretch the rope will be released as the rope returns to its original length. This release of energy could cause the poles of the windless to spin around causing injuries to any one near by. Natural fiber ropes, such as sisal, have little stretch; therefore are much safer to use.

MATERIALS:

1 - 8 foot * 3 inch pole
1 - 5 foot * 3 inch pole
1 - 3/4 inch * 50 foot (natural fiber)

SETUP:

STEP 1:

Tie one end of the rope to the load and the other end to a secure anchor point. Leave some slack in the rope so that the windless can be rigged.

STEP 2:

Follow the diagrams to set up the poles at the mid point of the rope.

STEP 3:

While one person holds the up right pole, a second person rotates the longer pole around the upright so that the rope begins to wrap around the upright pole. Adjust the height of the rope so that it can be easily stepped over.

STEP 4:

Continue to rotate the longer pole around the upright.

[NOTE]:

As the rope wraps around the upright it will be necessary to move the base of the upright to keep it vertical.

[NOTE]:

Be careful that the two ends of the rope are kept at the same level on the upright.

THIS MONTH'S IS THE :

ROPE HALTER

Start with an eye splice.
(The Eye splice will form one end of the nose piece of the halter)

Decide how long the nose piece must be then tie a quick eye into the rope.

Quick Eye STEP1

Decide where the quick eye must be. Then reeve the lead end through the lay of the rope as shown. (Slightly larger than the diameter of the rope)

Quick Eye STEP 2

Observe which strand of the lead end is directly under the strand of the nose piece end. Reeve the eye splice under that strand.

Quick Eye STEP 3

Work the eye into shape. (Do not just pull on the ends this will distort the eye.) When the eye is in shape, the strands of the rope should lay even showing little or no distortion.

Finnish the halter by reeving the lead end through the two eyes as shown.

© 2000, Gerald L. Findley

LADDER LASHING:

Comments:

Ladder lashing allows for a quick and secure method for constructing a ladder or for constructing a decking with evenly space decking pieces.

This form of lashing has several advantages over the traditional floor lashing. Less material is required because unlike floor lashing a space can be left between each piece of the decking. Also, each rung is securely lashed in place by several loops of rope in much the same way as a square lashing; with the traditional floor lashing only a single loop of the rope holds each end of the decking in place, therefore if one piece loosens, the entire deck loosens.

The ladder lashing has two forms; left and right, each is a mirror image of the other.

START: The ladder lashing is started by using a clove hitch stopped with two half hitches to secure a rope to the top end of each rail.

STEP 1: Lay an overhand loop over each side rail so that the running end of each loop is to the outside.

STEP 2: Place a rung across the rails so that the standing part of each overhand loop is over the end of the rung and the running part of each overhand loop is under the rung.

STEP 3: Pull the running part side of each overhand loop behind and to the outside of each rail.

STEP 4: Then pull the loop over the end of the rung.

STEP 5: Work each rope until it is tightened around the rung and the rung is in its desired position.

STEP 6: Form an overhand loop in each running part.

STEP 7: Place an overhand loop over each end of the rung to form a half hitch around each end of the rung.

STEP 8: Work the half hitch tight.

STEP 9: Repeat steps 1 through 8 for each additional rung.

END: Finnish the lashing by tying a clove hitch around each rail so that the clove hitch is directly under the bottom rung.

Quick Eye STEP 3

Work the eye into shape. (Do not just pull on the ends this will distort the eye.) When the eye is in shape, the strands of the rope should lay even showing little or no distortion.

Finnish the halter by reeving the lead end through the two eyes as shown.

SEIZING:

Use ---- To bind ropes together or to bind a rope to an object. Sometimes used to bind the running end of a rope to the standing end of the rope to prevent a knot from spilling.

Comments ---- Seizings do not use as much material and are not as bulky as a knot or a splice; nor does the seizing damage the fiber of the rope. The fibers of a rope do not need to be bent or separated to be seized as they do when a knot is being tied or a splice worked. If the seizing is no longer needed, the seizing can be cut away and the rope is undamaged.

The seizings shown here can be worked with out the use of a needle. However there are many forms of seizing that require the use of a needle to apply them to a rope.

To form an eye, 3 to 4 seizing should be used. This ensures that the eye will safely remain in place even if one of the seizings is damaged.

If there is additional strain on the ropes,

such as at the first seizing of an eye, racked turns should be used.

Materials ---- The diameter of the "twine" that is being used to do the seizing should be 1/8 to 1/12 the diameter of the rope being seized. The length of the "twine" should be about 3 feet for each 1 inch of diameter of the rope.

Narration ---- (For **seizing** knotboard.) **(1)** Fold a piece of twine in half over one strand of the rope. **(2)** Start the first layer of wrapping turns by laying the end of the twine that is between

---

the ropes over the other end. **(3)** Wrap the outside strand around the ropes so that so that the wrapping turns are parallel to each other; pull each wrapping turn tight. **(4)** When the width of the wrapping is equal to the diameter of the rope, end the first layer of wrapping turns by reeving the twine between the ropes; pull tight. **(5)** Add a layer of riding turns; the riding turns are laid in the grove between the wrapping turns and pulled tight but not so tight as to separate the wrapping turns of the first layer. **(6)** When the riding turns have been completed, end the riding turns by reeving the end of the twine between the ropes so that it is in the opposite direction to the other end of the twine. **(7)** Add frapping turns; reeve the end of the twine between the ropes at the other end of the wrappings; pull tight. **(8)** Use a square knot to end the frapping turns: reeve the ends of the twine between the

ropes again; tie a half knot; pull the half knot and the frapping turns tight. **(9)** Reeve the ends of the twine between the ropes again; tie the second half knot of the square knot. **(10)** Pull the second half knot tight so that the square knot is between the strands of the rope. Cut of the ends of the twine.

FIDS:

A fid is a tool that is used to open the lay of a rope when working a splice or to loosen knots.

MAKING A WOODEN FID:

Split out an 8 inch by 3/4 inch piece of close grained, smooth, hardwood. Carve and smooth the piece to the shape shown in the diagram.

MAKING METAL FIDS:

Materials:

1 --- 8 inch * 1/2 inch copper tubing or steel electrical conduit.

2 --- 1 inch diameter * 3 inch long piece of smooth grained hardwood.

2 --- 4D finishing nails.

Construction:

Cut the tubing diagonally into two pieces as shown in the diagram (Use a hacksaw).

Making a Closed Fid:

STEP 1: Use a triangular file to enlarge the diagonal opening in one of the halves of the tubing. File the opening to the shape indicated by the dotted lines in the diagram.

STEP 2: Close the diagonal opening. Using light taps with a hammer gently roll the two edges toward each other to form the tubing into a cone. (When the two edges of the opening meet the seam in the tubing should be straight).

STEP 3: Solder the edges of the opening together.

3A] Clean the edges of the opening with steel wool.

3B] Spread soldering paste along the cleaned edges.

3C] Solder the seam. Use a propane torch to apply heat to the side of the fid that is opposite the seam. (Heating the tube from the opposite side, will ensures that metal is heated all the way through so that the solder will flow into the seam and not just spread out on the surface.) As you heat the tubing test the seam for the proper temperature by touching the solder to the seam. When the solder starts to melt and flow into the seam, move the solder along the seam until the entire seam is filled with solder.

STEP 4: Cleanup the seam with steel-wool and a file. Make sure that there are no sharp edges to catch or cut the rope fibers when the fid is being used.

Making an Open Fid:

STEP 1: Enlarge the diagonal opening of the other piece of tubing by setting the tubing on end and forcing a rod into the opening. When the rod is forced into the opening, the cross section of the tubing should become "U" shaped.

STEP 2: With a round file, enlarge the diagonal opening to the shape shown by the dotted line.

STEP 3: Smooth all rough and sharp edges with a file and steel-wool.

STEP 4: Gently tap the edges of the opening toward each other so that a cross section anywhere along its entire length will be "U" shaped.

Making Handles For Fids:

STEP 1: Carve one end of a 1 inch diameter * 3 inch long piece of wood so that it will fit snugly into the end of the fid.

STEP 2: Attach handle to fid.

2A] Drill a small hole into the side of the fid about 1/2 inch from the end.

2B] Insert the handle into the end of the fid. Then drive a finishing nail through the hole into the wood of the handle.

2C] Cut the nail off close to the side of the fid. Then file the nail down so that it is smooth and even with the surface.

STEP 3: Finish the handle. Here is a chance to be creative. You can carve a simple rounded handle or let your imagination take over.

For a printout of the above go to....

MARLIN SPIKE HITCH:

Description A loop formed by a half hitch around a bight in the standing part of the rope.

Use To temporarily hold a toggle (a Marlin Spike) so that a rope can be pulled tight; as a mooring hitch that can be dropped over the end of a stake or pole; to hold the rungs of a rope ladder.

Comments A secure temporary hitch that can be easily spilled by removing the toggle. The Marlin Spike Hitch gets it name from the practice of using it around a Marlin Spike or similar tool to tighten knots and servicing,

Other Names Slip Noose; especially when the half hitch is pulled closed around the bight.

Narrative ---- (For **marlin spike** knotboard) **(1)** Form an overhand loop. **(2)**

Then form a bight in the standing part. **(3)** Place the bight under the overhand loop. **(4)** Then reeve the bight through the underhand loop. **(5)** Pass a toggle

FOOTROPE KNOT

Description: a three strand knot that looks somewhat like a turk's head knot.

Comments: This knot was tied in the "footrope" (the rope that was tied under the yard arm for the sailors to stand on when they were setting the sails) to prevent the sailors' feet from slipping along the footrope.

Use: as a stopper knot in the end of a rope.

STEP 1: Unlay 4 to 5 turns of the lay.

STEP 2: Tie a loose crown knot.

STEP 3:

STEP 4:

STEP 5:

STEP 6:

STEP 7: Tie a wall knot under the crown knot but tuck the strands up through the center of the crown knot.

STEP 8:

STEP 9:

STEP 10:

STEP 11:

STEP 12:

STEP 13: Work tight and finish by combing out the fibers to form a tassel of relay the strand and whip the end of the rope.

CAMP STOOL:

MATERIALS:

3 --- 2 Foot * 2 inch poles

20 --- 1/2 inch diameter sticks (various lengths)

1 --- 3/8 inch * 5 foot rope

1 --- 1/4 inch * 12foot rope

CONSTRUCTION:

STEP 1: Cut a grove 1 inch deep and 3/8 inch wide in each end of the 2 foot poles. Be sure that the groves are in the same direction.

STEP 2: Lash the 2 foot pole together at their centers with the 1/4 inch * 12 foot rope. Use the **equal shear tripod lash** shown here.

2A] Tie a clove hitch around one of the poles; secure the end by wrapping it around the standing end.

2B] Take 4 wraps around the 3 poles; follow the pattern shown for each wrap.

2C] Take 2 frapping turns behind each pole.

2D] End the lashing with a clove hitch around one of the poles.

2E] Set the tripod up by rotating each leg

STEP 3: Prepare the seat support rope by marking the middle of the 3/8 inch * 5 foot rope by tying a piece of twine around it. Then form a loop that has a 42 inch circumference by temporarily tying the ends of the rope together.

STEP 4: Place the seat support rope in the groves at the top of the poles so that the middle of the rope is in one of the groves. Adjust the ends poles so that they are evenly spaced around the loop.

STEP 5: Add the bracing rope. Tie a bowline into one end of the 1/4 inch * 10 foot rope. Then weave the rope back and forth between the ends of the tripod poles; follow the pattern shown in the diagram. End by tying a slippery half hitch through the eye of the bowline.

STEP 6: Assemble the seat.

6A] Lift one strand of the lay of the seat support rope on either side of the pole that is at the midpoint of the rope loop.

6B] Slide the ends of a 1/2 inch stick under the lifted strands of the seat support rope

6C] Lift the next strand of the lay of the rope on either side of the pole that is at the midpoint of the seat support rope

6C] Insert the next 1/2 inch stick**.**

[NOTE] To keep the ends of the tripod poles at a equal distance from each other as the seat is being constructed, the temporary knot that joins the two ends of the seat support rope will need to be retied several times.

6E] Continue in this manner until the seat is the desired size.

6F] Permanently join the 2 ends of the rope loop with a short splice.

6G] Trim the ends of the 1/2 inch sticks so that they extend about 2 1/2 inches beyond the rope.

[NOTE] By removing the 1/4 inch brace rope, this stool can be folded for transport and storage.

MONKEY'S PAW

(coil style)

(1) Form the first coil by stacking three loop on top of each other.

(2) Insert core into center of coil.

3) Start second coil by forming a small loop at the bottom of the first coil.

(4) Pass the running end behind and

(5) across the front to for the first loop of the second coil

(6) Add the second and third loops of the second coil.

---

(7) Start the third coil by reeving the running end through the top of the first coil and

---

(8) then reeve the running end through the bottom of the first coil.

---

(9) Add the second and third loops of the third coil.

---

(10) Work all coils tight over the core.

EXPLORE ROPEWORKS

Flag Pole Cleat:

A cleat is a device used to temporarily secure a line. When valuable equipment such as boat is being tied off, a commercially made cleat should be used. However, when a rustic appearance is desired a temporary cleat can be made with rope and wood.

Green Stick Cleat:

[Step 1] Round lash a piece of flexible green wood or a naturally curved piece of wood to the flag pole to make the horns of the cleat.

[Step 2] Tighten the round lashing by driving a small wedge on either side of the cleat.

[Step 3] Use frapping turns to raise the horns of the cleat.

Dry Wood Cleat:

Suggestion 1 ----

If only dry wood is available a cleat can be made as shown in the following diagrams:

[Step 1] Round lash a stick of suitable size to the flag pole to make the horns of the cleat.

[Step 2] Raise the horns by forcing short risers under each horn.

[Step 3] If needed tighten the round lashing by driving a small wedge on either side of the cleat.

Suggestion 2 ----

Preshape the cleat from a piece of limb wood .
[Step 1] Split a 3 inch diameter by 8 inch piece of limb wood in half.

[Step 2] Use an ax and knife to shape the horns on either end of split piece of wood.

[Step 3] Round lash the cleat to the flag pole.

[Step 4] Tighten the round lashing by driving a small wedge on either side of the cleat.

Precut Cleats:

A cleat can be made from hard wood lumber by sawing it to the desired shape and then round lashed to the flag pole. Small wedges are used on either side of the cleat to tighten the round lashing and to stabilize the cleat.

Making Wedges:

[Step 1] Cut to size. Length --- slightly longer than the width of the round lashing. Diameter --- slightly larger than the gap formed between the rope, the flag pole, and the cleat.

[Step 2] Cut one end off at an angle.

[Step 3] Taper the sides of the point so that the point of the wedge is on one side.

LE BORDER=0 CELLSPACING=0 CELLPADDING=0 LANG=en DIR=LTR WIDTH="612" COLS="8">

ROPE WRENCH:

A rope wrench is a simple tool that can be used to tighten the ropes of a lashing. Use a crochet stick that is about 18 inches long and 1 1/2 inches in diameter; the crotch should be about 6 inches from the end.

Using A Rope Wrench:

[STEP 1] Use the rope wrench by placing it over the pole next to the rope that is to be tightened.

[STEP 2] Wrap the rope around the fork of the wrench.

front view

back view

STEP 3] Make one or two wraps around the handle of the wrench.

front view

back view

[STEP 4] Grasp the handle so that you are holding the rope firmly to the handle; then rotate the wrench around the pole.

[NOTE] Tighten each turn of a lashing as it is made. The friction between the rope and the pole is too great to tighten more then one turn at a time.

Maintain the tightness of the rope by keeping a small amount of tension on it or by pressing the rope firmly against one of the poles while taking the next turn around the poles.

Be careful that the rope is not tightened so tight that the fibers of the rope begin to break.

NETTING:

The making of netting is an ancient craft. Many prehistoric cultures used netting for a verity of uses, storage bags, fencing, hammock, just to name some and of course the obvious use as a fish net. No matter what the netting was used for, the knitting of the mesh was done by tying a series of loops in some type of twine.

In one method, the basic knot used was the sheet bend. To form and tie the loops a knitting shuttle and a spacer (gauge) were used.

NETTING TOOLS:

The size of the shuttle and gauge that is needed will depend on the project that you are working on. The size of the shuttle and gauge given in the following directions is a convenient size for many projects and is also a good size to use for practicing the craft of netting. Shuttles and gauges of different sizes can be made by changing the size of the materials used.

Knitting Shuttle:

cross
sections

Make the knitting shuttle from a 1/4 inch * 1 inch * 12 inch piece of smooth grained hard wood. Carve and sand the shuttle to the shape shown in the diagram. Leave the shuttle unfinished; varnish or paint has a tendency to become sticky.

Knitting Gauge:

Make the knitting gauge from a 1/4 inch * 1 1/4 inch * 12 inch piece of smooth grained hard wood. Carve and sand the gauge to the shape shown in the diagram. Leave the gauge unfinished; varnish or paint has a tendency to become sticky.

Filling The Knitting Shuttle:

STEP 1: Fill the shuttle with twine. Start by tying a single hitch around the tongue of the shuttle and then pass the twine through the notch.

STEP 2: Turn the shuttle over, loop the twine around the tongue and then through the notch.

STEP 3: Continue turning the shuttle from side and looping the twine around the tongue until the shuttle is filled.

[NOTE] To prevent synthetic twine from fraying, use a candle flame to cut and fuse the ends.

[WARNING] Using a butane cigarette lighter to cut or fuse synthetic rope or twine may cause the lighter to over heat and explode.

DIAMOND MESH NETTING:

Diamond mesh netting is the easiest of the two forms of mesh to make. Square mesh netting will be dealt with latter.

Casting On: To start diamond mesh netting the first row of mesh loops is cast on to a loop of some kind. The kind of loop used depends on the project; a ring, grommet, frame, or loop of twine may be used. The following directions are for casting on to a ring but the same steps may be used for any starting loop.

STEP 1: Tie the end of the twine to the ring with a clove hitch stopped with two half hitches.

STEP 2: Place the twine behind the gauge then bring the twine in front of the gauge and to the right.

[NOTE]: The dotted circles in each of the diagrams is used to show the position of the thumb and finger of the left hand.

STEP 3: Reeve the twine through the ring from the front to the back so that an overhand loop is formed.

STEP 4: Pull the twine to the left to tighten the twine around the ring and the gauge.

STEP 5: Lay the twine across the ring from left to right.

STEP 6: Reeve the twine through the ring from the back to the front.

STEP 7: Place the twine behind the gauge; then pull the twine downward to tighten the twine around the ring. This forms a lark's head knot around the ring.

KNITTING A ROW OF MESH:

Netting is made by knitting roes of mesh using a shuttle and a gauge. The gauge is used to determine the size of the mesh, and the shuttle is used to hold the twine and form and tie the mesh loops. The basic knot used in netting is the sheet bend. The following diagrams illustrate the tying of the sheet bend as it is used for knitting a net.

STEP 1: Bring the twine down and up the back of the gauge. Then pick up the next loop by passing the shuttle through the loop from front to back.

STEP 2: Pull the twine to the left to tighten the twine around the gauge. Use the thumb and finger of the left hand to hold the twine in place.

STEP 3: Lay a loop of twine over the loop just picked up.

STEP 4: Pass the shuttle in back of the picked up loop and the through the loop that was laid on top.

STEP 5: Pull the twine downward and slightly to the right to tighten the knot.

STEP 6: Repeat steps 1 through 5 for each loop in the row.

STARTING A NEW ROW:

STEP 1: When the end of a row of mesh is reached, slide the accumulated loops off the gauge, turn the work piece over so that the running end of the twine is on the left side of the work piece.

STEP 2: Wrap the twine around the gauge from front to back; pick up the first loop by passing the shuttle through the loop from back to front.

STEP 3: Knit the loop in place by following the directions for knitting a row of mesh.

ADDING A LOOP:

For some projects it is necessary to increase the width of the netting part way through the project. The width of the netting is increased by adding loops of mesh.

A loop is added by picking up the same loop a second time so that two loops are formed in the new row of mesh are tied to the same loop in the previous row of mesh.

PROLONG KNOT

DESCRIPTION:

A flat knot that is made by interweaving two strands of rope.

USE:

As stair tread, mat, or chafing gear; also as a decorative knot in a two strand lanyard.

COMMENTS:

The prolong knot gets its name from the fact that it can be extended to any length.

TYING:

STEP 1:

Place the center of the rope over a peg or hook and tie a loose half knot.

STEP 2:

Extend the half knot as shown.

STEP 3:

Twist the left loop and extend it to the right side.

[NOTE] This will start the over under pattern

of the weaving.

STEP 4:

Twist the right loop and extend it to the left side so that it is over the first extended loop.

STEP 5:

Weave the left strand to the right in the pattern shown.

STEP 6:

Weave the right strand to the left in the pattern shown.

[NOTE] This completes the four bight prolong knot. At this stage it may be ended and worked firm (over tightening distorts the knot) or the strands my be doubbled as shown in later diagrams.

STEP 7:

Twist the left loop and extend it to the right side.

STEP 8:

Twist the right loop and extend it to the left side so that it is over the first extended loop.

STEP 9:

Weave the right strand to the left in the pattern shown.

STEP 10:

Weave the left strand to the right in the pattern shown. This completes the 7 bight form of the prolong knot.

[NOTE] The prolong knot can be extended three bights at a time by repeating steps 7 through 10 for each extension.

STEP 11:

Start doubling the strands by chacing (following) the opposite strand.

STEP 12:

Complete doubling the strands. Then work the knot into a firm mat . Do not over tighten the strands as this will distort the mat.

[NOTE] The ends of the strands can be hidden by sewing them to the adjacent strand on the underside of the mat.

1996, Gerald L. Findley

LIFE BASKET:

Description ---- A body harness made by combining a bowline on a bight and a french bowline.

Use ---- To lower a severally injured person when a life threatening situation exists.

Comments ---- The life basket is a secure harness that can be used to move an injured person that is weakened or unconscious. However, unless there is a life threatening situation, such as a burning building or immediate danger of avalanche, you should wait for a trained rescue team.

If you attempt to use the life basket, do not allow the rope to slide through your hands as you lower the injured person . The friction caused by the sliding rope can cause severe painful rope burns and loss of control of the rope. The rope must be let out in a hand over hand manner to insure a safe, controlled descent.

1.

Narration ---- (1) Tie a bowline on a bight. Place one loop of the bowline on a bight around each leg. [NOTE] (The bowline on a bight should be large enough so that when it is in place the knot should be close to the victims belt buckle. Be sure to leave the running part of the rope extending about 3 feet beyond the knot.)

2.

(2) Take a half hitch around the victims chest.

(3) Form a bight in the standing part by pulling it under the right hand part of the half hitch so that an underhand loop is formed around the cross point of the half hitch.

(4) Fold the bight around and reeve it through the eye of the underhand loop.

(5) Reeve the running part of the rope through the bight.

(6) Take the slack out of the running part of the rope and fold the it over to form interlocking bights.

(7) Pull on the standing part so that the bight in the running part of the rope is pulled through the eye of the underhand loop and the underhand loop flips over and tightens around the bight to form a French Bowline.

SPHERICAL KNOB COVERING

This knot is used to cover knobs. One example would be to cover a knob at the end of a walking stick.

The length of cord needed to tie the knob covering knot depends on the size of the cord and the number of times the pattern is to be chased. A good length to start with is 8 times the circumference of the knob for each time the pattern is to be chased. [Example: a one inch knob has a circumference of a little over 3 inches. To cover a one inch knob it would require about 25 inches of cord for each time the pattern is chased. The pattern should be chased at least 2 times.

This means that about 50 inches of cord would be used to cover a 1 inch knob.

The knob covering knot is difficult to tie "in hand" the easiest method of tying it is to make a copy of the diagram and fasten the diagram to a work board. Start by pinning the middle of the cord to the feathered end of the arrow in the diagram. Then following the path indicated, pin the cord to the diagram. Be sure to follow the over/under pattern indicated in the diagram. Studying the following partial diagrams may help.

After the knot is tied on the work board unpin it and work it loosely into shape over the knob. Then chase the pattern the required number of times. Next work the knot tight around the knob. Do not rush this stage. When the knot is tight cut off the ends of the cord and push the ends into the knot.

To preserve the knot, it may be varnished or painted.

Walking Stick:

Carve a knob on the end of the walking stick.

If desired, the size of the knob can be increased by wrapping it with tape.

Tie the covering knot and work it tight over the knob.

CROWN KNOT:

Use ---- To tie of the end of a rope so that it does not unlay. ----- To begin a back splice. ---- As part of several multiple strand knots.

---

(1) Tie off the rope 6 complete lays from the end.

(2) Unlay the rope to the tied off point.

(3) Place the end of one of the unlayed strand between the other two unlayed strands;

(4) press the strand firmly between the strands so that a loop is formed. **[NOTE]** As you are looking at the end of the rope work counterclockwise around the rope .

(5) Fold the second strand over the first strand. **[NOTE]** This will hold the loop in the first strand in place.

(6) Reeve the end of the third strand through the eye of the loop.

---

(7) Fold the third strand over the second strand. **[NOTE]** This will hold the second strand in place.

(8) Pull the loop closed. **[NOTE]** Work and pull all three strands until the knot is even and symmetrical.

WALL KNOT

Use ---- To tie of the end of a rope so that it does not unlay. ---- As part of several multiple strand knots.

---

(1) Tie off the rope 6 complete lays from the end

(2) Unlay the rope to the tied off point.

NOTE: work the knot in a counterclockwise direction as you look at the end of the rope.

(3) Place the end of one of the unlayed strands under the strand to its left. (Hold the loop open as you work the knot).

---

(4) Place the second strand under the first and tthird strand.

(5) Placce the third strand under the second strand.

---

(6) Reeve the end of the third strand up through the loop formed in the first strand.

[A]

[B]

---

(7) work tight.

ALAMAR KNOT

The alamar knot is a decorative knot related to the pretzel knot. The pretzel knot is tied in a single strand; the alamar knot is tied by doubling the strands as showwn in [Step 1]

[Step 1] Double the strand as shown.

[Sterp 2]

[Sterp3]

[Step 4]

[Step 5] Add tassels or other end decorations.

BOWLINE ON A BIGHT:

Description ---- A double loop bowline Tied by interlocking a doubled half hitch and a bight.

Use ---- As a nonslip double loop; as a loop any where along the length of a rope; as secure loop for rescue work; as the start of a life basket harness; as a emergency boatswain chair.

Comments ---- The bowline on a bight is a secure double loop that can be tied anywhere along the length of a rope. Several can be used as a "dead eyes" for tightening a rope when securing a load or guy line.

Narration ---- (For **bowline on a bight** knot-board.) **(1)** Take a bight in the rope. **(2)** Using the bight as the running part, make a double strand overhand loop. **(3)** Take the running part under the overhand loop. This forms a double strand bight that will become the eye of the knot. (4) Reeve the running part through the eye of the overhand loop. **(5)** Spread the eye of the running part (bight). **(6)** Pull the running part (bight) through the overhand loop

6.

7.

8.

9.

(back)

until you can enlarge it enough **(7)** to pass it over the double strand bight. **(8)** When the eye of the running part (bight) is around the standing part, **(9)** Grasp the double loop bight and the standing part and pull the knot tight.

[NOTES]

CLOVE HITCH:

Description —- Two single hitches (half hitches) tied in the same direction around an object.

Uses —-To secure a line to a post or pole; to start and end most lashings.

Comments — Can be untied (spilled) by pulling on the standing part so that it rotates the cross point in the knot until it goes over the end of the rope.

The length of the standing part can be adjusted by rotating the loops of the knot around the pole. To shorten the standing part, pull on the running end so that it rotates the cross point toward the standing end . To lengthen the standing part, pull on the standing part so that the cross point is rotated toward the running part.

Because the clove hitch can be spilled by rotating the standing part against the cross point, the clove hitch will spill itself if it is tied so that standing part moves back and forth in such a way that it cause the loops of the knot to slide around the pole. To prevent the clove hitch from spilling, 'stop' it by tying two half hitches around the standing part.

STOPPED CLOVE HITCH

When under constant tension the clove hitch has little tendency to slide along the length of the pole even if the tension is nearly parallel to the pole.

Narrative ---- (For **clove hitch** knotboard.) **(1)** Start the clove hitch by taking a bight around an object with the running part. **(2)** Cross the running part over the standing part to form a half hitch. **(3)** Start the second half hitch by continuing to wrap the standing part around the object in the same direction as the first half hitch. **(4)** Form a second bight around the object. **(5)** Finish the second half hitch**. (6)&(7)** Grasp the standing part and the running part: pull tight the clove hitch tight.

CLOVE HITCH; OVER AN END:

A clove hitch can be tied over the end of a pole or stake by using this method.

(1) Form two underhand loops in the running part of the rope.

(2) Place the right underhand loop on top of the left underhand loop.

(3) Drop the loops over the end of the pole.

(4) Pull tight.

SQUARE LASHING:

Use ---- To bind poles that are in contact and cross each other at any angle from 45° to 90°.

Comments ---- The square lashing gets it name from the fact that the wrapping turns are at 90° or "square" to the poles.

Traditional square lashing is the most frequently used and the most secure form of lashing. If tied properly, the square lashing will remain tight and secure, but, as with all lashings, if any steps are omitted or done carelessly, the lashing will loosen and create a dangerous situation.

The square lashing can be used to bind poles together that cross and contact each other at any angle from 45° to 90°. If the angle of contact is greater than 45°, a shear lashing should be used.

When tying a square lashing, the poles and the rope must be positioned properly to achieve the maximum strength. The cross pole should

be position so that the force applied to the cross pole is directed toward the pole it is lashed to; this allows the wood to wood contact to bare part of the lode; if the force tends to separate the poles, only the rope will be supporting the load. The beginning clove hitch should be tied to the pole that is closest to parallel to the direction of the force and to the side of the cross pole that is opposite to the direction of the force. In most cases the force applied to a structure is due to gravity, therefore downward, this means that the beginning clove hitch is usually tied to the vertical pole, and under the cross pole. The standing end of the rope is secured by wrapping it around the running end.

Narration ------ (For **square lash** knotboard.) **(1)** Tie a clove hitch to the vertical pole. **(2)** Wrap the standing end of the rope around the running end **[NOTE]** The wrapping of the standing part around the running part is to secure the clove hitch so that it will not slip around the pole and loosen the lashing from the inside. **(3)** Bring the running end up and over the cross pole; then around the vertical pole; and back down over the cross pole. **(4)** Pass the rope behind the vertical pole and back up in front of the cross pole; this completes the first wrapping. **[NOTE]** Notice that the rope goes around the pole perpendicular, at 90°, to the length of the pole. This 90° angle gives the square lashing its name. **(5)** Take two more wrapping turns for a total of three wrappings: pull each turn tight. **[NOTE]** When the wrappings are taken around the vertical pole the rope should be to the inside of the previous wrapping turn; and the wrappings around the cross pole should be to the outside of the previous wrapping turn. When this pattern of taking the wrapping turns is followed the rope strands remain parallel; this insures the maximum contact between the wood and the rope. Also if the strands are not kept parallel, the additional friction between the crossed strands will make it difficult to properly tighten the wrapping turns. **(6)** Start the frapping turns by taking one

complete turn around the cross pole; **[NOTE]** The turn around the cross pole prevents the rope from crossing the wrapping turns on a diagonal. If the change of direction between the wrapping turns and the frapping turns is made by passing the rope diagonally across the wrapping turns, the increased friction between the rope strands will make it difficult to pull the wrapping turns tight. A diagonal across the wrapping turns will also allow unnecessary movement within the completed lashing, which could cause chaffing of the rope. **(7)** Take at least two frapping turns; keep the turns parallel to each other; pull each turn tight as it is made. **[NOTE]** Keeping the frapping turns parallel prevents unnecessary friction between the turns making it easier to tighten the frapping turns. **(8)** When the last frapping turn is in place, take a half hitch around the cross pole, work the half hitch tight. **[NOTE]** To prevent the rope from crossing the wrapping turns diagonally when tying the half hitch, take the rope past the cross pole on the same plain as the frapping turns, then around the cross pole. **[NOTE]** To work the half hitch tight, first pull the running end toward the standing end. This will tighten the frapping turns. Next, while keeping tension on the running end pull it in the opposite direction so that the loop of the half hitch will slip around the pole. This takes up any slack left in the rope. Work the running end back and forth in this way until the half hitch is locked tight against the lashing. If this half hitch is not locked against the lashing the ending clove hitch can slip around the pole allowing the lashing to loosen. **(9)** Add a second half hitch to form a clove hitch around the cross pole; work half hitch tight.

[NOTE] If smooth rope is being used a third half hitch added to the clove hitch will help insure that the lashing will stay securely in place.

© 1999, Gerald L. Findley

SQUARE LASHING

EYE SPLICE:

Use ---- To form a permanent loop or eye in the end of a rope.

Comments ---- The loop formed by a well made eye splice maintains 85% or more of the original strength of the rope; this makes the eye splice the preferred way to form an permanent loop in the end of a rope. However if the eye is to be subjected to repeated chafing, such as a rope being pulled through it, the eye should be serviced with a wear resistant twine.

Narration ---- (For **eye splice** knotboard) **(1)&(2)** Count back and unlay 5 rounds of the lay of the rope. **(3)** Fan the unlayed end of the rope and place it over the standing part of the rope. The strand to the inside of the eye must look like it is coming out from under the other two strands and the other two strands must be fanned in such a way that they do not cross each other. **(4)** While holding the inside strand in place, stick the middle strand under one of the strands of the standing end of the rope.

EYE SPLICE

1.

2.

3.

4.

5.

6.

7.

8B.

8F.

(5) Pass the inside strand over the standing end strand and stick it under the next standing end strand. **[N0TE]** The second strand goes in where the first strand came out. **(6)** Turn the splice over. (**7)** Stick the third strand under the remaining strand of the standing end. **[NOTE]** The third strand is stuck in where the second strand came out and comes out where the first strand went in. **[NOTE]** When the third strand is stuck it appears to go backward but when it is examined closely you will see that it is stuck in the same direction as the other two strands. **(8B) & (8F)** Complete the splice by working the strands snug and adding 3 to 5 50unds of tucks.

[NOTE] When the strands are folded back over the eye, you will notice that there is one strand going in and one strand coming out between each of the strands of the standing end.

TURK'S HEAD:

Description ---- Three strand braid worked in a continuous circle.

Use ---- **(1)** As a decorative knot around a staff or railing. **(2)** Worked tight around a checked or cracked tool handle or canoe paddle to reinforce them. **(3)** As a neckerchief slide or wogal.

Comments ---- The form of Turks head shown here is a five crown Turk's head, this is only one of a group of knots that go by the name Turk's heads.

The crown number is determined by counting the number of bights at the edge of the knot. To make a larger loop, increase the size of the wraps made in steps 1 - 4 and then, at step 7 use three strand braiding to increase the number of crowns. The number of crowns can be increased by increments of three; so that the number of crowns in a larger loop can be 8, 11, 14, etc..

The size of the finished Turk's Head depends on the size of the rope used and the number of times the strand is chased.

Other Names ---- Three lead by five bight Turk's head, ordinary Turk's head.

Narration ------ (For Turk**'s head** knotboard.) **(1)** Start at the center of the line, by taking a bight around an object (the fingers of the left hand work well) **(2)** Complete the round turn and cross the running end over the standing end. **(3)** Take a second bight around the object so that the running end is between the standing end and the first wrap. **(4)** Lay the running end across the first wrap then **(5)** tuck the running end under the standing end. **(6)** lay the standing end across the second wrap and **(7)** tuck it under the first wrap. **(8)** rotate the knot around the object so that you are looking at the opposite side. **(9)** Cross the second wrap over the first wrap. **(10)** Reeve the standing end through the eye formed between the two wraps. **(11)** Reeve the running end through the eye between the two wraps so that the ends are in opposite directions. **(12)** Chase, follow, the strand of the knot two or three times. Cut off and secure the ends.

[NOTE] To determine the length of line to use, wrap the line around the object four times for a single strand knot. Add three and one half wraps for each time you intend to chase the original strand.

RINGBOLT HITCHING:

Description ---- A series interlocking lark's head knot that form a ridge around the outside of a ring or loop.

Use ---- To prevent chafing; as a decoration.

Comments ---- There are many forms of ringbolt hitching, the form shown here is one of the simplest and does not require the use of a needle as many other forms do. Ringbolt hitching was used to prevent chafing of ropes that were reeved through hand forged iron rings and to keep them from clanging against objects around them. In the present, ringbolt hitching can be used to protect synthetic ropes that are easily chafed by a applying a layer of material that is not easily chafed.

Other Names ---- Platted Ring; Hog Backing; Cockscombing.

Narration ----- (For **ringbolt hitching** knotboard.) **(1)** Start the ringbolt hitching by tying a half knot around the object. **(2)** Tie a half hitch around the object so that the standing end is trapped under the half hitch. **(3)** pull the half hitch tight. **(4)** Tie the next half hitch in the opposite direction around the object. **(5)** Pull the half hitch tight. **(6)** Tie another half hitch in the opposite direction around the object; the same direction as the first half hitch. **(7)** Pull

© 1999, Gerald L. Findley

half hitch tight. **(8)** When the length of the ring-bolt hitching is within 5 or 6 half hitches of being long enough; form a bight in the a short piece of twine so that the eye of the bight is toward the end of the work. **(9)** Continue to add half hitches until the ringbolt hitching is completed; reeve the running end through the eye of the bight. **(10)** Use the short piece of twine to pull the running end under the half hitches. **(11)** Cut off the end of the twine.

[NOTES]

BOATSWAIN'S WHISTLE KNOT

Description ---- A two lead knot that is built up from two interlocking underhand loops to looks like a turk's head knot when it is worked tight.

Use ---- As a decorative knot to attach a whistle or a knife to a lanyard ---- to form a toggle or button.

Other names ---- Sailor's knife lanyard knot, marlingspike lanyard knot, single-strand diamond knot, two strand diamond knot ---- pipe lanyard knot.

Narration ----(For **boatswain's whistle knot** knot-board.) **(1)** Use the left hand to hold the middle of a strand of rope so that the loop of the bight is to the back of the hand and the two leads are between the fingers and hanging down across the palm. **(2)** Use the bottom lead, to lay an underhand loop over the standing end of top lead. **(3)** Form a bight in the bottom lead so that its running end is under the running end of the top lead. **(4)** Weave the running end of the bottom lead over the right edge of the top underhand loop, then under the standing end of the bottom lead, and over the left edge of the top underhand hand loop. This forms two interlocking underhand loops. **(5)** Form the next bight by placing the running end of the top lead under the top edge of the top underhand loop. **(6)** Reeve the running end of the top lead to the outside of the standing end of the bottom lead and up through the middle of the interlocking underhand knots. **(7)** Form the next bight by placing the running end of the bottom lead under the bottom edge of the bottom underhand loop. **(8)** Reeve the running end of bottom lead to the outside of the standing end of the bottom lead and up through the middle of the interlocking underhand knots. **(9)** Work the knot tight.

Doubling:

Doubling the Boatswain's Whistle Knot increases its size. The increase in size makes it more effective as a toggle or button. Doubling also gives a variation in appearance when doing decorative work.

Doubling Continued:

Narrative ---- (For **Doubling** knotboard.) **(1)** Follow steps 1 --- 4 from the knot board for the BOATSWAIN'S WHISTLE KNOT. (**2**) Form the next bight by placing the running end of the top lead under the top edge of the top underhand loop. **(3)** weave the running end of the top lead to the inside of the standing end of the bottom lead and across the middle of the interlocking underhand knots. **(4)** Form the next bight by placing the running end of the bottom lead under the bottom edge of the bottom underhand loop. **(5)** Weave the running end of bottom lead to the inside of the standing end of the bottom lead and across middle of the interlocking underhand knots. **(6)** Chase the top lead with the bottom lead; end by bringing the top lead up through the middle. (7) Chase the bottom lead with the top lead; end by bringing the bottom lead up through the middle. **(8)** Work the knot tight.

8.

DIAGONAL LASHING:

Use ---- Diagonal lashing is used to bind poles together that cross each other but do not touch when their ends are lashed in place in a structure.

Comments ---- The diagonal lashing gets its name from the fact that the wrapping turns cross the poles diagonally.

The diagonal lashing can be used to bind poles that cross each other from 90° to 45°. If the angle between the poles is less than 45° a shear lashing should be used.

The diagonal lashing makes use of the timber hitch to pull poles together that are not touching each other. The timber hitch allows the poles to be drawn together without changing the relative positions of the poles. **[NOTE]** If a square lashing were used to bind poles that do not touch, the beginning clove hitch would pull the cross pole toward the clove hitch causing unnecessary bowing of the cross pole and could also produce a force that would act along the length of the pole to which the clove hitch is tied. These additional force, if strong enough, can place unnecessary strain on other lashing within the structure causing the structure to twist and fail.

Narration ---- (For **diagonal lash** knotboard.) **(1)** Tie a timber hitch diagonally around both poles. **(2)** Start the wrapping turns on the opposite diagonal to the timber hitch, by pulling the rope tight so that the poles contact each other. **(3)** Take 3 to 4 wrapping turns; keep the wrapping turns parallel; pull each wrapping turn tight. [NOTE] If the wrapping turns are allowed to cross, the increased friction between the strands of the rope will make it difficult to tighten the wrapping turns. **(4)** Start the second set of wrapping turns by going past and around the vertical pole. **[NOTE]** Going

around the pole the rope allows the direction of the rope to be changed without crossing the first set of wrapping diagonally. **(5)** Take 3 to 4 wrapping turns; be sure to keep the wrapping turns parallel; pull each wrapping turn tight. **(6)** Start the frapping turns by going past and around one of the poles. **[NOTE]** Going around the pole with the rope allows the direction of the rope to be changed without crossing the wrapping turns diagonally. **(7)** Take 2 to 3 frapping turns; keep the frapping turns parallel. Be sure to pull each turn tight. **(8)** End the lashing with a clove hitch. Take the first half hitch of the clove hitch by going past and then around one of the poles. Lock the half hitch tight against the lashing by working it tight. **(9)** Take a second half hitch around the pole. **(10)** Work the second half hitch tight against the first half hitch so that the clove hitch is locked against the lashing.

[NOTE] See the directions for square lashing for instructions on working the half hitches tight.

[NOTE] If very smooth rope is used, the lashing can be made more secure by adding a third or forth half hitch to the clove hitch.

© 1999, Gerald L. Findley

CONSTRICTOR KNOT:

Description ---- A clove hitch with a half knot under the cross-point.

Use ---- To tie a smaller rope to a larger one, or to tie a rope to a stake or pole; a substitute for whipping; as a lashing for light construction ; as a hose clamp.

Comments ---- A secure nonslip knot ; difficult to untie without cutting.

METHODS OF TYING:

Method # 1:

[NOTE] Use this method of tying the constrictor knot on either side of where you intend to cut a rope. This is a fast and easy way to prevent a rope from unlaying when it is cut.

Narration ---- (For **constrictor knot (method #1)** knotboard.) (1) take a bight around an pole. **(2)** Continue wrapping the running part around the pole so that the running part crosses over the standing part. **(3)** Complete the turn around the pole. **(4)** Cross the running part over the standing part so that **(5)** a bight is formed around the standing part. **(6)** Reeve the running part under the cross part of the loop in the standing part to form a half knot under the cross-point. **(7)** Pull the standing tight. **(8)** Lock the knot tight by pulling hard on both the standing part and the running part.

© 1999, Gerald L. Findley

METHODS OF TYING:

Method # 2: Over the end of a pole or rope.

[1] Start with an underhand loop laid on the pole.

[2] Place the loop over the end of the pole.

[3] Pull the opposite side of the loop down and under the cross point of the underhand loop

© 1999, Gerald L. Findley

[4] ..... then pull it up and over the end of the pole .....

[5] ..... to form a second loop around the pole and a half knot under the cross point of the knot.

[6] Pull the two ends tight. The harder you pull the tighter the knot.

Method # 3: Slippery constrictor knot.

[NOTE] This method of tying the constrictor knot allows it to be untied quickly and easily.

© 1999, Gerald L. Findley

Narration -----(For **slippery constrictor knot** knotboard.) **(1)** Tie the slippery constrictor knot the same way as a regular constrictor knot but **(2)** form a bight in the running end before it is **(3)** reeved under the cross part of the loop in the standing part. Pull the standing tight. **(4)** Lock the half knot tight by pulling hard on both the standing part and the running part.

Method # 4: As a lashing.

SUGGESTED USES: For the constrictor knot.

whipping

spaced rungs

tying to a stake or pole

round lashing

MONKEY'S PAW:

Description ---- Theform of the monkey's paw sown here is formed from four interlocking loops: a four crown turk's head.

Use ---- The core determines what the monkey's paw can be used for. When tied over a stone or heavy ball, the monkey's paw can be used to add weight to a heaving line. If tied over a cork ball with small cord the monkey's paw makes a good float for boat keys or other small items used around a water front. Tied over a ball of twine or other soft material, the monkey's paw can be used as weight on the end of a rope for the game jump the shot. A Monkey's Paw can also be used as a toggle.

Core Size ----- The diameter of the core should be between three and four diameters of the rope being used.

MONKEY'S PAW TURK'S HEAD

Narration ---- (For **monkey's paw turk's head** knotboard) **(1)** Form an overhand loop **(2)** Form a second overhand loop over the left edge of the first overhand loop . **(3)** Cross the standing end over the running end. **(4)** Weave the running end across the loops by placing the running end over the right side of the top loop **(5)** then under the right side of the bottom loop **(6)** next, over the left side of the top loop **(7)** and

6.

7.

8.

9.

10. chase 2 to 3 times

11. work tight over a core

finally under the left side of the of the bottom loop. **(8)** Pull the running end through until a third loop equal in size to the first two loops. **(9)** Add the fourth loop by placing the running end parallel to the standing end. **(10)** Chase the original pattern 2 to 3 times. **(11)** Work tight over the core.

[NOTE] Join the two ends of the monkey's paw with an eye splice, a short splice, or a seizing.

© 1999, Gerald L. Findley

MOORING HITCH :

Description —— An underhand loop toggled to the standing part with a bight made in the running end.

Use —— To securely tie off a rope so that it can be quickly untied, especially a small boat to a dock or piling.

Comments —— A secure knot that is easily tied or untied in wet or dry rope; when properly tied a non closing loop is formed, this allows the hitch to move up or down a piling as the water level changes.

Narrative ——(For **mooring hitch** knotboard.) **(1)** Take a bight around an object. **(2)** Form an underhand loop in the running part. **(3)** Place the eye of the underhand loop over the standing part. **(4)** Pull a bight of the standing part through the eye of the underhand loop. **(5)** Pull the underhand loop tight around the bight. **(6)** Place the running part under the eye of the bight that was pulled through the underhand loop. **(7)** Pull a bight of the running part through the eye of the standing part bight. **(8)** Pull on the standing part to tighten the standing part bight around the running part bight.

© 1999, Gerald L. Findley

[NOTES]

JUG KNOT:

Use ---- to provide a convenient carrying handle for jug or bottle ---- to attach a tool, such as a hammer to a security line to prevent accidental dropping --- to add a wrist loop to a walking staff --- to attach a safety line to a canoe paddle ..... use your imagination, but be sure that you keep safety in mind.

Other names ---- Jar knot, moonshiner's knot, hackamore, bridle knot.

Comments ---- The most common use is to provide a loop handle attached to the neck of a bottle. The loop handle makes it easy to carry several bottles with one hand. If a toggle or a two strand button knot such as boatswain whistle knot is added to the free end of the rope,

JUG KNOT

1.

2.

fold down

3.

cross loops

4.

The loop of the jug knot can be use to toggle the bottle to a belt so that the bottle can be use as a canteen.

Plastic bottles with screw-on lids such as soda, sport drink, and mineral water bottles make strong, lightweight containers for carrying water on hikes and camp outs. 2 and 3 liter soda bottles are large enough to use as water containers around the camp kitchen. Smaller bottles (8 to 16 oz.) can be used as personal water bottles or canteens. These bottles can be made even more convenient by using a jug knot to attach a loop handle.

To help keep your water cool and refreshing in hot weather, place a sock over the bottle, wet the sock when you fill the bottle, evaporation will do the rest.

In cold weather, carry your water bottle under your coat. A dry sock placed over the bottle will help keep the water from freezing.

To protect your health, wash and disinfect your water bottle with a chlorine bleach solution and don't share your water bottle with others; show them how to make a water bottle of their own.

Narrative ---- (For **jug knot** knotboard) **(1)** Form a bight in the middle of a 24 to 30 inch long by 3/16 inch diameter rope. **(2)** Fold the bight down over the standing ends to form two loops. **(3)** Place the right loop over the side of the left loop. **(4)** Weave the middle of the bight under the standing end; then over the left edge of the right loop; **(6)** next go under the right edge of the left loop; **(7)** finally pass the bight over the right side of the left loop. **(8)** Turn the tops of the original loops down over the knot. **(9)** Place the knot over the neck of a bottle and work the knot tight so that the bight forms a 4 to 5 inch loop handle and the loose ends are even.

BELAYING TO A CLEAT:

Description ----- A turn secured to a cleat with a figure eights and locked in place with a half hitch.

Use ---- To secure a flag lanyard, to moor a boat to a dock.

Comments ---- Belaying to a cleat is a fast non-jamming method of securing a rope anywhere along its length without reeving any part of the rope through or around anything.

Narration ----(For **belaying to a cleat** knotboard.) **(1)** Take a bight around the the first horn of the cleat and pull the line tight. **(2)** Take a bight around the second horn. **(3)** Place the line across the cleat. **(4)** Take a second bight around the first horn. **(5)** Place the line across the cleat a second time. **(6)** Form a loop so that its running end is under its standing end. **(7)** Place the eye of the loop over the second horn of the cleat. **(8)**Pull the loop tight to form a half hitch around the horn of the cleat, this locks the rope in place.

© 2000, Gerald L. Findley

5. cross cleat

6. form loop

7. place over horn

8. pull half hitch tight

KNOTBOARD CLEAT PATTERN:

Use this pattern to make 8 hardwood cleats. Attach the cleats to the knotboard with 1 1/2 inch number 8 round head wood screws.

WHIPPING:

Description ---- Twine wrapped and secured to the end of a rope.

Use ---- To prevent the fraying of the end of a rope.

Comments ---- Even though "whipping" is done in several different ways, the finished "whippings" have similar appearance: the ends are secured under the turns, the length of the whipping is equal to the diameter of the rope, and all turns are parallel.

Synthetic rope, rope made of plastic, should be whipped and fused to prevent the rope from fraying. Fusing helps to hold the whipping in place and the whipping helps to prevent the fused rope strands from braking apart.

Other Names ---- Serving: When a rope is wrapped with twine to prevent chafing or wearing; the wrapping is done using the similar methods to whipping. ---- **Seizing:** When twine is wrapped around two or more strands of rope to hold the rope in place; the wrapping is done using methods similar to shear lashing.

Materials ---- The twine that is used for whipping should be tightly spun or braided twine that is less then 1/8 the size of the rope to be whipped. Twine made of synthetic material should be used to whip synthetic rope, if natural fiber twine is used, the capillary action along the fibers of the rope draw water under the whipping causing the whipping to remain damp, so that rot quickly sets in. Likewise, natural fiber twine should be used to whip natural fiber rope, the poor wicking action of synthetic fibers allowing the whipping to trap moisture in the natural fiber rope, causing the rope to rot.

WHIPPING: METHOD 1:

Narration ----- (For **whipping [method 1]** knotboard.) **(1)** Form a loop in a 12 inch piece of twine so that the ends of the twine are parallel and in opposite directions. Lay the loop on the end of the rope so that the ends of the twine and the rope are all parallel and one end of the twine is extending beyond the end of the rope. **(2)** While holding the twine in place between the thumb and forefinger, pass the loop of twine around the end of the rope so that the wrap is with the lay of the rope. **(3)** To finish the wrapping, pull the twine under the thumb so that the twine is wrapped toward the standing part of the rope, pull the twine tight. **(4)** While holding the last wrapping in place between the thumb and forefinger, add additional wraps by passing the loop of twine around the end of the rope and pulling the wrap tight under the thumb for each wrap. **(5)** Continue to add wraps until the length of the whipping is equal to the diameter of the rope. **(6)** While still holding the last wrap tight between the thumb and forefinger, pull the loop closed by pulling on the end of the twine that is sticking out past the end of the rope. **(7)** Tighten the whipping by pulling on both ends of the twine. **(8)** Finish the whipping by cutting off the ends of the twine.

WHIPPING: METHOD 3

Narration ----(For **whipping [method 3]** knot-board.) **(1)** Form a bight in a 6 inch piece of twine; lay the bight parallel to the end of the rope with the ends of the twine extending past the end of the rope. **(2)** Lay the end of a 24 inch piece of twine next to the loop with the long end extending past the end of the rope. **(3)** Take a wrap around the end of the rope; hold the bight and the wrap in place with the thumb and forefinger; pull wrap tight. **(4)** When the length of the whipping is equal to the diameter of the rope, reeve the end of the twine through the eye of the bight. **(5)** Use the bight to pull the free end of the twine under the wrappings. **(6)** Tighten the whipping by pulling on the ends of the twine. **(7)** Finish the whipping by cutting off the end of the twine.

BOUND WHIPPING:

Description ---- A whipping with strands across the wraps.

Use ---- As a secure permanent whipping.

Comments ---- Bound whipping secures the wrapping turns by adding frapping turns to a standard whipping.

Other Names ---- Sailmaker's Whipping, (usually done with a needle).

Tying a Bound Whipping:

STEP 1: Lay a loop formed from a 24 inch piece of twine in one of the grooves between the strands of the rope. The end of the twine toward the standing part of the rope should be about 3 inches long.

© 1999, Gerald L. Findley

STEP 2: Wrap the twine around the end of the rope, work toward the standing part of the rope.

STEP 3: When the length of the whipping is equal to the diameter of the rope, close the loop by pulling on the end of the twine that extends beyond the end of the rope.

STEP 4: Pull on both ends of the twine to tighten the whipping around the rope.

STEP 5: Separate the ends of the rope strands, pull the twine between the strand to the right of the groove that the twine was originally laid in and the other two strands.

STEP 6: Use a fid to lift the strand of the rope as shown in the diagram (this is the same strand that the twine went around at the end of the rope), reeve the twine under the strand; pull twine tight.

STEP 7: Lay the twine over the original groove and then pull the twine between the ends of the rope strands so that the twine is around the rope strand to the left of the original groove; pull twine tight.

STEP 8: Use a fid to lift the rope strand as shown in the diagram (this is the same strand that the twine went around at the end of the rope); reeve the ends of the twine through the opening and tie a half knot as shown in the diagram; pull twine tight.

STEP 9: Reeve the ends of the twine through the opening again; tie a second half knot in the opposite direction as shown in the diagram; pull twine tight to form a square knot.

STEP 10: Remove the fid and trim the ends of the twine close to the surface of the rope.

[NOTE] If synthetic rope and twine were used the ends of the rope and the twine may be fused.

FIGURE-EIGHT KNOT:

Description ---- Interlocking overhand loops, the running part goes through the eye of one loop and the standing part goes through the eye of the other loop.

Use ---- (1) As a stopper knot; to keep a rope from unreeving from a pulley block; to prevent a rope from unlaying. **(2)** When tied on a bight, makes a reliable loop for rescue work and mountaineering.

Comments ---- Easier to tie and untie than an overhand knot; does not damage the rope fiber or jam like an overhand knot.

Narration ---- (For **figure eight** knotboard.) **(1)** Form an overhand loop. **(2)** Take a bight around the standing part. **(3)** Form the second overhand loop by bring the running part over the top edge of the firs overhand loop. **(4)** Complete the knot by reeving the running part through the eye of the first overhand loop **(5)** and pull tight.

FIGURE EIGHT ON A BIGHT:

Description ---- Interlocking overhand loops tied on a bight in the running part (the bight is used as the running part); the running part goes through the eye of one loop and the standing part goes through the eye of the other loop.

Use ---- (1) Makes a reliable loop for rescue work and mountaineering. **(2)** As a stopper knot; to keep a rope from unreeving from a pulley block; to prevent a rope from unlaying.

Comments ---- Easier to tie and untie than an overhand knot; does not damage the rope fiber or jam like an overhand knot on a bight.

Narration ---- (For **figure eight on a bight** knotboard.) **(1)** Form a bight in the rope. **[NOTE]** Treat the two strands of the bight as a single strand as the rest of the knot is tied. **(2)** Form an overhand loop. **(3)** Take a bight around the standing part. **(4)** Form the second overhand loop by bring the running part over the top edge of the firs overhand loop. **(5)** Complete the knot by reeving the running part through the eye of the first overhand loop **(6)** and pull tight.

[NOTE]

TRIPOD LASHING:

Description ---- A shear lashing around 3 poles.

Use ---- To bind three poles together, for the construction of a tripod. ---- To bind three poles together that contact at the same point in a structure.

Comments ----The tripod lashing is a shear lashing that binds three poles together at the same point. ---- The tripod lashing gets it name from the fact that its most common use is the construction of a tripod. ----The tripod lashing can be used just about any where in a structure that three poles cross each other at the same point and the same time in the sequence of construction. ---- Tripod lashing takes two main forms; with racked wrapping turns (the rope is woven between the poles) and with plain wrapping turns (the rope is wrapped around the poles without weaving the rope between the poles). When the lashing is made with racking turns the rope contacts each pole around its entire circumference ; this contact makes the tripod lashing with racking turns the most secure form of tripod lashing: therefore tripod lashing with racking turns should be used when safety is important. However, for light structures where there would be no danger if the lashing slipped, the faster to tie tripod lashing with plain wrapping turns may be used.

Laying Out The Poles ---- For most tripod lashings, lay the pole side by side with the butt ends aligned. The alignment of the butts of the pole insures that the tripod legs are the desired length.

[NOTE] The practice of laying the center pole in the opposite direction to the outside poles creates several problems. When the poles are laid in opposite directions the wrappings must be put on loosely so that when the center pole is rotated to its proper position the lashing is tightened around the poles. If the wrappings are put on to tight, the rope is stretched causing damage to the rope fibers, therefore weakening the lashing. On the other hand, if the rope is wrapped two loosely, the lashing will not tighten enough when the center pole is rotated and the lashing will be able to slip along the length of the pole. Either way, the rope to loose or the rope to tight, a dangerous situation is created.

However, if the tripod is to be part of a structure and the center pole will be at an angle greater then 90° to the outside poles, lay the center pole in the opposite direction to the outside poles so that the rotation of the poles at the lashing is less then 90°. See gate way below for an example.

© 1999, Gerald L. Findley

Setting Up A Tripod ----- Set up the tripod by crossing the outside poles so that the cross point of the poles is under the center pole. Crossing the outside poles under the center pole causes part of the load that is placed on the tripod to be taken up by the wood to wood contact of the poles.

If the outside poles are crossed above the center pole, the rope of the lashing will be required to support all or most of the load; therefore the tripod will not be as strong as when the outside legs are crossed under the lashing.

no wood to wood contact, rope supports load

If a symmetrical arrangement of the poles is needed within a structure, the tripod can be set up by rotating the poles around the lashing. This rotation cause the loss of the wood to wood contact so that the load is supported only by the ropes, and the joint between the poles becomes very flexible; therefore the tripod may be unstable.

TRIPOD LASHING: (With Racking Turns)

Narration ---- (For **tripod lashing with racking turns** knotboard.) **(1)** Tie a clove hitch around one of the outside poles. **(2)** Secure the standing part by wrapping it around the running part. **[NOTE]** Wrapping the standing part around the running part prevents the clove hitch from slipping around the pole. If the clove hitch slips the lashing will loosen up from the inside. **(3)** Start the racked wrapping turns by weaving the rope between the poles. **(4)** Take a total of 5 to 7 wrapping turns. Pull each wrapping turn tight as it is made. **[NOTE]** The stiffness of the tripod lashing depends on the number and tightness of the wrapping turns. As the tightness of the wrapping turns or the number of wrapping turns increases, the stiffness of the tripod will increase. **(5)** Take the first frapping turn by taking the rope around the pole that the clove hitch

was tied to, then between the outside pole and the center pole. **(6)** Take 3 frapping turns. Pull each frapping turn tight as it is made. **(7)** Start the second set of frapping turns by taking the rope across the center pole and reeving it between the second outside pole and the center pole. Take the second set of frapping turns in the opposite direction to the first set of frapping turns. **[NOTE]** Taking the second set of frapping turns in the opposite direction to the first set of frapping turns prevents the rope from crossing the wrappings at a diagonal. Unnecessary crossing of the rope increases friction between the strands of the rope making it difficult to tighten the lashing properly. **(8)** Take a total of 3 frapping turns. Pull each turn tight. **(9)** Take the first half hitch of the ending clove hitch around the second outside pole by taking the rope past the pole and then around the pole. **(10)** Work the half hitch tight so that it is locked against the lashing. **[NOTE]** See the narration for square lashing for instructions on working the half hitch tight. **(11)** Take the second half hitch of the ending clove hitch. **(12)** Work the half hitch tight to complete the ending clove hitch. **[NOTE]** If the clove hitch is not worked tight so that it is locked against the lashing the clove hitch will slip around the pole allowing the lashing to loosen. **[NOTE]** If very smooth rope is being used, a 3rd half hitch should be added to the clove hitch to insure that the lashing will stay in place.

TRIPOD LASHING: (WITH PLAIN TURNS)

Narration ---- (For **tripod lashing with plain turns** knotboard.) **(1)** Tie a clove hitch around one of the outside poles. **(2)** Secure the standing part by wrapping it around the running part. **[NOTE]** Wrapping the standing part around the running part prevents the clove hitch from slipping around the pole. If the clove hitch slips the lashing will loosen up from the inside. **(3)** Start the wrapping turns by wrapping the rope around the poles. Take a total of 4 to 6 wrapping turns. Pull each wrapping turn tight as it is made. **[NOTE]** The stiffness of the tripod lashing depends on the number and tightness of the wrapping turns. As the tightness of the

wrapping turns or the number of wrapping turns increases, the stiffness of the tripod will increase. **(4)** Take the first frapping turn by passing the rope around the pole that the clove hitch was tied to, then between the outside pole and the center pole. **(5)** Take 2 or 3 frapping turns. Pull each frapping turn tight as it is made. **(6)** Start the second set of frapping turns by taking the rope around the center pole and reeving it between the second outside pole and the center pole. **(7)** Take the second set of frapping turns in the opposite direction to the first set of frapping turns. **[NOTE]** Taking the second set of frapping turns in the opposite direction to the first set of frapping turns prevents the rope from crossing the wrappings at a diagonal. Unnecessary crossing of the rope increases friction between the strands of the rope making it difficult to tighten the lashing properly. **(8)** Take a total of 2 or 3 frapping turns. Pull each turn tight. **(9)** Take the first half hitch of the ending clove hitch around the second outside pole by taking the rope past the pole and then around the pole. Work the half hitch tight so that it is locked against the lashing. **[NOTE]** See the narration for square lashing for instructions on working the half hitch tight. **(10)** Take the second half hitch of the ending clove hitch. Work the half hitch tight to complete the ending clove hitch. **[NOTE]** If the clove hitch is not worked tight so that it is locked against the lashing the clove hitch will slip around the pole allowing the lashing to loosen. **[NOTE]** If very smooth rope is being used, a 3rd half hitch should be added to the clove hitch to insure that the lashing will stay in place.

© 1999, Gerald L. Findley

QUICK TRIPOD LASHING:

Comments ---- The tripod quick lash is one of the fastest ways to construct a tripod. However the tripod quick lash is not as secure as the more conventional methods, therefore the tripod quick lash tripod should not be use for heavy loads.

Directions -----

STEP 1] Lay the poles side by side with the with the butt ends alined. Wrap 5 to 8 wrappings around all three poles.

STEP 2] Start the frapping turn by taking each end around an outside pole and then between the outside pole and the center pole.

STEP 3] Take 1 or 2 frapping turns with each end. Pull the frapping turns tight; this will also tighten the wrappings.

[NOTE] The frapping turns are taken in opposite directions.

STEP 4] End the lashing by tying the ends of the rope together with a square knot.

[WARNING]

If one end of the square knot is pulled it can be up set into a lark's head knot. When this happens the knot will slip causing the entire lashing to loosen and fail.

SHEET BEND:

Description ---- An interlocked bight and half hitch.

Use ---- To temporarily join two ropes, especially if the ropes are of different sizes.

Comments ---- The sheet bend is a secure but easily untied knot. ---- When tying the sheet bend the running parts should be left long because there is some initial slip in the knot when the knot is first brought under tension. ---- The proper and more secure way to tie the sheet bend is so that the two end the rope are on the same side of the knot.

Other Names ---- Weavers knot

Related Knots ---- Bowline; becket hitch; these knots share the same form but are tied in a different way or have a different use.

Narrative ---- (For **sheet bend** knotboard.) **(1)** Form a bight in the running part of the left-hand rope. **(2)** Reeve the running part of the right-hand rope through the eye of the bight in the left-hand rope. **(3)** With the right-hand running part take a bight around the running part and the standing part of the left-hand rope. **(4)** Pass the right-hand running part over the left-hand standing part, **(5)** under the right-hand rope, and **(6)** over the standing part of the left-hand rope. **(7)** Pull tight.

opposite side

WEAVER'S KNOT:

Description ---- A different method of tying a sheet bend.

Use ---- For joining light twine and yarn together, especially by weavers.

Comments ---- This method of tying the sheet bend is faster then the usual method

.

Narration ------ (For **weaver's knot** knotboard.) **(1)** Cross the left-hand running part over the right-hand running part. Hold this cross point together between the thumb and first finger of the left hand. **(2)** With the right hand, grasp the right-hand standing part and make a loop over the thumb and **(3)** between the standing parts so as to form a half hitch around the left-hand rope. **(4)** Fold the running part of the left-hand rope back along itself to form a bight around the standing part of the right-hand rope. **(5)** Reeve the running part of the left-hand rope through the eye of the half hitch and pull the knot tight to complete the knot.

BECKET HITCH:

Description ---- A half hitch tied around a permanent eye, such as the eye of an eye splice or a hook.

Use ---- To tie a rope to an eye splice, a hook or a ring.

Comments The becket hitch has the sane form as the sheet bend but is used to tie a rope to an eye or hook, whereas the sheet bend is used to join two ropes.

DOUBLE SHEET BEND:

Comments ---- This method of tying the sheet bend is the most secure form of the sheet bend and should be used if there is a significant difference in the sizes of the two ropes that are being used.

Narrative ---- (For **double sheet bend** knotboard.) **(1)** Form a bight in the larger of the two ropes. **(2)** Reeve the smaller rope through the eye of the bight. **(3)** Then take a bight around the part of the larger rope; be sure to take the bight from the standing part side to the running part side. **(4)** Bring the running part of the smaller rope over the larger rope and **(5)** under the smaller rope to form a half hitch around the two parts of the bight in the larger rope. This forms the first turn. **(6)** Take a second bight around the larger rope. **(7)** Again bring the smaller rope over the larger rope and under the smaller rope to complete the second turn. **(8)** Pull tight.

[NOTE] If the difference in the sizes of the ropes is significant or the ropes are very smooth, additional turns of the smaller rope will help to prevent the ropes from slipping.

<----- pull tight ------->

SHEET BEND ON A SHORT END:

Use ---- For joining light rope, twine, thread, and yarn.

Comments ---- This method of tying the sheet bend is useful for tying a piece of rope onto another rope when the end of the rope is very short.

Narrative ---- (For **sheet bend on a short end** knotboard.) **(1)** Form an overhand loop. **(2)** Fold the loop over onto its standing part. **(3)** Pull a bight of the standing part through the loop to form an overhand knot in the running part. **(4)** Pull on the standing part and the running part of the overhand knot to close the eye around the standing part to form a slip noose. **(5)** Place the eye of the slip noose over the running part of the second rope. **(6)** Pull on the running part of the first rope and push on the overhand knot to upset the slip noose so that a bight of the second rope is pulled through the overhand loop to form the sheet bend. **(7)** Pull on the standing parts of each rope to tighten the sheet bend.

MASTHEAD KNOT:

Comments ----There are several forms of the Masthead Knot, two of which are shown here. The first form of the Masthead Knot was chosen for its symmetry and the ease of transition to the running half hitches used to secure it to the pole. The second form was chosen for the ease with which it can be tied.

Use ----On board ship, a masthead knot was used to rig a temporary mast if the mast was lost in battle or during a storm. On land a masthead knot can be used to rig a gin pole or a flag pole.

Other names ---- Jury mast knot, pitcher knot.

MASTHEAD KNOT (1):

Description ---- A multiple loop knot formed by reeving the loosely made loops of two over hand knots through each other and then securing the knot to a mast (pole).

Narration ----- (For **masthead knot (1)** knotboard.) **(1)** Loosely tie two over hand knots. **(2)** Place the loop of one overhand knot on top of the loop of the loop of the other over hand knot. **(3&4)** Reeve the loops of the overhand knot through the half knot part of the opposite overhand knot. **(5)** Place over a pole and draw the three loops up even. **(6)** Secure to the pole with a series of running half hitches above and below the mast head knot.

[NOTE] A forth loop my be formed by tying or splicing the ends together. If a fourth loop is made, nail a cleats to the pole to prevent the mast head knot from slipping.

[NOTE] Attach the guy lines to the loops with becket hitches.

4.

5. place over pole and draw up even

6. secure to pole with running half hitches

MASTHEAD KNOT (2):

Description ---- A multiple loop knot formed by weaving three overlapping over hand loops together and then securing the knot to a mast.

Narration ----- (For **masthead knot (2)** knotboard.) **(1)** Form an over hand loop near the center of the rope. **[NOTE]** The size of the loop is determined by the size of the pole that the finished knot is to be placed over. **(2)** Form a second larger overhand loop at the center of the rope. **(3)** Place the left edge of the second overhand loop under the right edge of the first overhand loop. **(4)** Form a third overhand loop. **(5)** place the left edge of the third overhand loop under the right edge of the second over hand loop. **(6)** Start weaving the over hand loops together by placing the left edge of the right overhand loop on top of the right edge of the left over hand loop. **(7)** Continue the weaving by placing the right edge of the left overhand loop over the right edge of the center overhand loop and by placing the left edge of the right overhand loop under the left edge of the center overhand loop. **(8)** Finish the weaving by placing the right edge of the left overhand loop under the right edge of the right overhand loop and by placing the left edge of the right overhand loop over the left edge of the left overhand loop. **(9)** Place over pole and work tight. The knot is prevented from slipping down the pole by nailing cleats to the pole or by cutting a grove for the knot to rest in. **(10)** Secure the ends of the rope by seizing them to the adjacent loop; two half hitches my also be used.

[NOTE] A forth loop my be formed by tying or splicing the ends together.

[NOTE] Attach the guy lines to the loops with becket hitches.

FLOOR LASHING:

Use ---- to lash a series of poles to a set of stringers to form a flat surface such as a deck, a table top, or a road way.

Comments ---- When using a floor lashing, both ends of the decking poles must be lashed at the same tine to insure a firm even surface.

When placing the decking poles on the stringers, lay the decking poles so that their butt end are in alternating direction. Alternating the but ends of the decking poles will compensate for the natural taper of the poles so that the length of the decking along each stringer will be equal.

Narration ---- (For **floor lashing** knotboard) **(1)** Tie a clove hitch around each stringer. **(2)** Secure the short end of the rope by wrapping it around the running end (wrap with the lay of the rope). **(3)** Place the decking poles on the stringers and take a bight around the first pole. **(4) Next,** on the inside of the stringer, pull a bight up between the first decking pole and the next decking pole. **(5)** Place the eye of the bight over the end of the decking pole. **(6)** Pull tight. **(7)** On the outside of the stringer, place a bight over the next decking pole. **(8)** Pull tight. **(9)** Repeat steps 4 through 8 until all decking poles are lashed in place. **(10)** Tie the first half hitch of the ending clove hitch. Work half hitch tight. **(11)** Tie the second half hitch of the ending clove hitch. Work half hitch tight **(12)** to form clove hitch.

7.

Mauls:

A maul is a wooden club or hammer that is used for driving stakes or wedges and for safety reasons should be used instead of an ax.

Using an ax instead of a maul exposes the user to the danger of being cut by its sharp edge. Even if the edge is covered by a sheath, a glancing blow can cause the sheath to be ripped off or to be cut through.

The pole of an ax serves as a counterweight to the blade. This counterweight adds to the balance of the ax head and helps to control and increase the force of momentum delivered to the bit. The ax head is shaped in such a way that the momentum of the ax head is delivered through the thin walls of the eye. However, when an ax is being used as a hammer, this same shape causes the eye of the ax head to spread and the handle to loosen.

The flat surface and angular edges of an ax pole makes it difficult to strike a stake squarely. This difficulty in striking a square blow results in most blows delivering some there force sideways, causing the end of the wooden stake to flare and split very quickly. In addition, when the pole of an ax contacts a stake, the metal surface of the pole lacks the ability absorb any of the force of the impact this contributes to the destruction of the stake. A wooden maul, on the other hand, absorbs some of the impact of the initial contact and a maul has no angular edges. Therefore, more of the force of the maul is used to do useful work and less of the force is used up in deforming or splitting the stake.

Making a Club Maul:

A club maul, for driving tent pegs and other light work, can be made from a piece of hardwood that is about 3 inches in diameter and 18 to 24 inches long.

|----------18" to 24" ----------|

|---- 4" to 5" ---|

STEP 1: Use an ax to rough out the maul. Form a handle by cutting away one end of the piece of wood so that it is about 1 1/4 inches in diameter. Leave 4 to 5 inches of the other end at its original diameter to form the head of the maul.

STEP 2: Smooth the handle with a knife.

MAKING A HAMMER MAUL:

Materials:

To make the head of a hammer maul you will need a 4 inch diameter, 10 inch long piece of hard, dense, unchecked, well seasoned, hardwood such as elm, black gum or hophornbeam.

For the handle you will need a piece of well seasoned ash, hickory, or similar straight grained wood; 1 1/2 inch diameter and 3 to 4 foot long.

Making a Maul:

STEP1: Square the ends of the head with a saw.

STEP 2: Find and mark the midline between the two ends.

STEP 3: Locate the center of the handle hole on each side of the maul head.

[3A] Wrap a strip of paper around the maul head. Cut the strip of paper off so that the two ends just meet.

[3B] Locate handle hole by folding the strip of paper in half to mark its mid point, then unfold it and wrap it around the maul head again. Mark the midline at the fold and at the ends of the strip of paper.

STEP 4: Drill handle hole in head. Use a 1 1/4 inch drill bit to drill a hole halfway through the head from one side, then finish drilling the hole from the other side of the maul head.

[NOTE] If the holes do not lineup in the middle use a chisel or wood rasp to cut away some of the excess wood.

STEP 5: Make maul handle.

5A] Cut a saw kerft in the one end of the handle. The depth of the kerft should be equal to 1/2 the diameter of the maul head.

5B] Use a knife to shave the end of the handle down until it can be easily driven through the head with light blows with a light wooden block.

STEP 6: Attach the maul head to the handle.

6A] Make a hardwood wedge that is 1 1/4 inch wide, 3 inches long, and 1/4 inch thick at its large end.

6B] Drive the handle into the maul head, make sure that the saw kerft is lined up across the maul head.

6C] Then drive the wedge in place.

© 1999, Gerald L. Findley

STEP 7: Reinforce the maul head to keep it from splitting by wrapping several turns of rope or wire around each end of the maul head. These can be held in place with staples.

Another method of reinforcing the head would be to drive a braided ring or a grommet over each end of the head.

[NOTES]

MAUL --- DOVE TAIL HANDLE:

MATERIALS:

1 ----- Piece of seasoned hardwood that is 2 2/2 to 3 inches in diameter and 5 to 7 inches long for the head.
1 ----- piece of seasoned hardwood that is 1 1/2 inches to 2 inches in diameter for the handle.

CONSTRUCTION:

STEP 1: With a saw, cut 3 kerfts as shown at the center of the side of the head.

|----------|
Less than the diameter of the handle

[NOTE] The width of the bottom of the dovetail notch must be less than the diameter of the handle.

STEP 2: Use a knife or chisel to remove the wood to form the dovetail notch.

STEP 3: Shape and fit handle to head.

3A] Flatten one side of the end of the handle.

[1] Equal to or greater than the width of the bottom of the dovetail notch.

[2] Equal to or less than the depth of the dovetail notch.

[3] Equal to the diameter of the head.

3B] Fit the handle to the bottom of the dovetail notch. Gradually remove the surplus wood until the flattened part of the handle is the same width as the width of the dove tail notch.

3B] Flatten the remaining two sides of the handle. Gradually remove the surplus wood until the handle fits snugly into the dovetail notch in the head.

3A] Tap handle firmly into dovetail notch.

ROPE WRENCH:

The dovetail maul makes a good rope wrench. Pass the rope over the head of the maul and then take several wraps around the handle. The rope is then tightened by rotating the maul so that the rope wraps part way around the head of the maul.

FUSING:

The ends of a synthetic rope can be fused to prevent the rope from fraying. This is done by heating the end of the rope so that the ends of the rope fibers melt together.

The fusing can be done by holding the end of the rope to the side of a candle or other small flame. If the end of the rope is placed in the flame or held too close to the flame, the plastic will ignite causing the end of the rope to turn black. Burning plastic can also give off toxic fumes . If the end of the rope is held above the flame, unburned carbon particle will be deposited on the melted plastic causing it to turn black. A candle flame will generate enough heat to fuse the end of a rope up to about one inch in diameter. If the rope is larger than one inch, a propane torch will work better .

[WARNING] Do not use a butane cigarette lighter to fuse rope. A butane lighter can explode if it is permitted to burn too long.

[NOTE] If the rope is cut to length with a soldering iron or other hot cutting tool, the ends of the rope will be fused as the rope is being cut to length.

A small lamp such as an alcohol lamp or a small oil lamp works very well for fusing rope.

© 1999, Gerald L. Findley

TAUT-LINE HITCH:

Description —— Two half hitches with an extra turn.

Use —— To adjust the tension on guy lines.

Comments —— The tension is adjusted by sliding the knot along the standing part of the rope.

To decrease the tension on a guy line, grasp the standing part just out side the loop, then slid the knot away from your hand.

Other Names —— There are several other names that are used interchangeable for the taut-line hitch and several related knots. The midshipman's hitch, rolling hitch, and magnus hitch. The following seems to be the most common usage of these name:

When tied around its own standing part ----**taut line hitch**.

rolling hitch

When tied around an object other then its own standing part ---- rolling hitc**h, magnus hitch.**

midshipman's hitch

When tied so that the second turn is between the first turn and the standing part ---- **midshipman's hitch** (see direction for midshipman's hitch).

adjustable jam hitch

When tied with the two turns outside the loop and the half hitch inside the loop ---- **adjustable jam hitch.**

Use --- To tie-up a bundle so that the knot can be tightened by sliding the knot toward the bundle and loosened by sliding the knot away from the bundle.

© 1999, Gerald L. Findley

TAUT-LINE HITCH

© 1999, Gerald L. Findley

Narrative ---- (For **taut-line hitch** knotboard.) **(1)** Take a bight around the pole. **(2)** Take a bight around the standing part. **(3)** (The eye of the bight becomes the eye of the taut-line hitch) Pass the running part through the eye of the aut-line hitch (between standing part and the pole) this forms a half hitch around the standing part**;** pull tight **(4)** Take a second bight around the standing part in the same direction; **(5)** this results in two complete turns around the standing part. **(6)** Pull tight. **(7)** Go to the outside of the loop. **(8)** Take another bight around the standing part; pass the running part between itself and the first half hitch, **(9)** this forms the second half hitch, **(10)** Pull tight.

[NOTES]

MIDSHIPMAN'S HITCH:

Description ---- Two half hitches with an overlapping extra turn.

Use ---- To adjust the tension on a guy line when very smooth rope is being used.

Comments ---- The midshipman's hitch is harder to adjust then the taut-ine hitch, therefor it is the ideal knot for adjusting the tension on synthetic rope guy lines.

Narrative ----

(1) After taking a bight around an object, take a turn around the standing part so that the turn is inside the loop.

(2) Take a second turn around the standing part so that the running end crosses the first turn and is between the first turn and the beginning of the knot.

(3) Pull the second turn tight to lock it in place.

(4) Take a half hitch around the standing part so that it is outside the loop.

(5) Opposite side.

SPANISH WINDLESS:

A Spanish windless is a device for moving heavy loads such as rocks and logs.

[WARNING] When setting up a Spanish Windless do not use nylon or other synthetic fiber rope that stretch under a load. If you slip or let go of the poles the energy you used to stretch the rope will be released as the rope returns to its original length. This release of energy could cause the poles of the windless to spin around causing injuries to any one near by. Natural fiber ropes, such as sisal, have little stretch; therefore are much safer to use.

MATERIALS:

1 — 8 foot * 3 inch pole
1 — 5 foot * 3 inch pole
1 — 3/4 inch * 50 foot (natural fiber)

SETUP:

STEP 1: Tie one end of the rope to the load and the other end to a secure anchor point. Leave some slack in the rope so that the windless can be rigged.

STEP 2: Follow the diagrams to set up the poles at the mid point of the rope.

STEP 3: While one person holds the up right pole, a second person rotates the longer pole around the upright so that the rope begins to wrap around the upright pole. Adjust the height of the rope so that it can be easily stepped over.

© 1996, Gerald L. Findley

STEP 4: Continue to rotate the longer pole around the upright.

NOTE] As the rope wraps around the upright it will be necessary to move the base of the upright to keep it vertical.

NOTE] Be careful that the two end of the rope are kept at the same level on the upright.

keep rope at
same level

[NOTES]

ROPE HALTER

Start with an eye splice.

(The Eye splice will form one end of the nose piece of the halter)

Decide how long the nose piece must be then tie a quick eye into the rope.

Quick Eye STEP1

Decide where the quick eye must be. Then reeve the lead end through the lay of the rope as shown. (Slightly larger than the diameter of the rope)

Quick Eye STEP 2

Observe which strand of the lead end is directly under the strand of the nose piece end. Reeve the eye splice under that strand.

Quick Eye STEP 3

Work the eye into shape. (Do not just pull on the ends this will distort the eye.) When the eye is in shape, the strands of the rope should lay even showing little or no distortion.

Finnish the halter by reeving the lead end through the two eyes as shown.

© 2000, Gerald L. Findley

LADDER LASHING:

Comments:

Ladder lashing allows for a quick and secure method for constructing a ladder or for constructing a decking with evenly space decking pieces.

This form of lashing has several advantages over the traditional floor lashing. Less material is required because unlike floor lashing a space can be left between each piece of the decking. Also, each rung is securely lashed in place by several loops of rope in much the same way as a square lashing; with the traditional floor lashing only a single loop of the rope holds each end of the decking in place, therefore if one piece loosens, the entire deck loosens.

The ladder lashing has two forms; left and right, each is a mirror image of the other.

START: The ladder lashing is started by using a clove hitch stopped with two half hitches to secure a rope to the top end of each rail.

STEP 1: Lay an overhand loop over each side rail so that the running end of each loop is to the outside.

STEP 2: Place a rung across the rails so that the standing part of each overhand loop is over the end of the rung and the running part of each overhand loop is under the rung.

STEP 3: Pull the running part side of each overhand loop behind and to the outside of each rail.

STEP 4: Then pull the loop over the end of the rung.

STEP 5: Work each rope until it is tightened around the rung and the rung is in its desired position.

STEP 6: Form an overhand loop in each running part.

STEP 7: Place an overhand loop over each end of the rung to form a half hitch around each end of the rung.

STEP 8: Work the half hitch tight.

STEP 9: Repeat steps 1 through 8 for each additional rung.

END: Finnish the lashing by tying a clove hitch around each rail so that the clove hitch is directly under the bottom rung.

SEIZING:

Use ---- To bind ropes together or to bind a rope to an object. Sometimes used to bind the running end of a rope to the standing end of the rope to prevent a knot from spilling.

Comments ---- Seizings do not use as much material and are not as bulky as a knot or a splice; nor does the seizing damage the fiber of the rope. The fibers of a rope do not need to be bent or separated to be seized as they do when a knot is being tied or a splice worked. If the seizing is no longer needed, the seizing can be cut away and the rope is undamaged.

The seizings shown here can be worked with out the use of a needle. However there are many forms of seizing that require the use of a needle to apply them to a rope.

To form an eye, 3 to 4 seizing should be used. This ensures that the eye will safely remain in place even if one of the seizings is damaged.

If there is additional strain on the ropes, such as at the first seizing of an eye, racked turns should be used.

Materials ---- The diameter of the "twine" that is being used to do the seizing should be 1/8 to 1/12 the diameter of the rope being seized. The length of the "twine" should be about 3 feet for each 1 inch of diameter of the rope.

Narration ---- (For **seizing** knotboard.) **(1)** Fold a piece of twine in half over one strand of the rope. **(2)** Start the first layer of wrapping turns by laying the end of the twine that is between the ropes over the other end. **(3)** Wrap the outside strand around the ropes so that so that the wrapping turns are parallel to each other; pull each wrapping turn tight. **(4)** When the width of the wrapping is equal to the diameter of the rope, end the first layer of wrapping turns by reeving the twine between the ropes; pull tight. **(5)** Add a layer of riding turns; the riding turns are laid in the grove between the wrapping turns and pulled tight but not so tight as to separate the wrapping turns of the first layer. **(6)** When the riding turns have been completed, end the riding turns by reeving the end of the twine between the ropes so that it is in the opposite direction to the other end of the twine. **(7)** Add frapping turns; reeve the end of the twine between the ropes at the other end of the wrappings; pull tight. **(8)** Use a square knot to end the frapping turns: reeve the ends of the twine between the ropes again; tie a half knot; pull the half knot and the frapping turns tight. **(9)** Reeve the ends of the twine between the ropes again; tie the second half knot of the square knot. **(10)** Pull the second half knot tight so that the square knot is between the strands of the rope. Cut of the ends of the twine.

SEIZING:
WITH RACKING TURNS

Narration ---- (For **seizing with racking turns** knotboard.) **(1)** At the center of a piece of twine, tie a half knot so that the twine is around the first rope and the half knot is between the ropes. **(2)** Take racking turns with the twine by taking a bight around the second rope and reeving the twine between the ropes; **(3)** then take a bight around the first rope and reeve the twine between the ropes again. (each racking turn forms a figure "8" around the rope. **(4)** When the length of the layer of racking turns is equal to the diameter of the rope, end the layer of racking turns with a half hitch around the second rope. **(5)** work half hitch tight. **(6)** Add a layer of riding turns; the riding turns are laid in the grove between the wrapping turns and pulled tight but not so tight as to separate the wrapping turns of the first layer. **(7)** Add frapping turns; reeve the end of the twine between the ropes at the other end of the wrappings; pull tight. **(8)** Use a square knot to end the frapping turns: reeve the ends of the twine between the ropes again; tie first half knot of the square knot; pull the half knot and the frapping turns tight. **(9)** Reeve the ends of the twine between the ropes again; tie the second half knot of the square knot. **(10)** Pull the second half knot tight so that the square knot is between the strands of the rope. Cut of the ends of the twine.

[NOTES]

FIDS:

A fid is a tool that is used to open the lay of a rope when working a splice or to loosen knots.

MAKING A WOODEN FID:

Split out an 8 inch by 3/4 inch piece of close grained, smooth, hardwood. Carve and smooth the piece to the shape shown in the diagram.

MAKING METAL FIDS:

Materials:

1 --- 8 inch * 1/2 inch copper tubing or steel electrical conduit.
2 --- 1 inch diameter * 3 inch long piece of smooth grained hardwood.
2 --- 4D finishing nails.

Construction:

Cut the tubing diagonally into two pieces as shown in the diagram (Use a hacksaw).

Making a Closed Fid:

STEP 1: Use a triangular file to enlarge the diagonal opening in one of the halves of the tubing. File the opening to the shape indicated by the dotted lines in the diagram.

STEP 2: Close the diagonal opening. Using light taps with a hammer gently roll the two edges toward each other to form the tubing into a cone. (When the two edges of the opening meet the seam in the tubing should be straight).

© 1999, Gerald L. Findley

STEP 3: Solder the edges of the opening together.

3A] Clean the edges of the opening with steel wool.

3B] Spread soldering paste along the cleaned edges.

3C] Solder the seam. Use a propane torch to apply heat to the side of the fid that is opposite the seam. (Heating the tube from the opposite side, will ensures that metal is heated all the way through so that the solder will flow into the seam and not just spread out on the surface.) As you heat the tubing test the seam for the proper temperature by touching the solder to the seam. When the solder starts to melt and flow into the seam, move the solder along the seam until the entire seam is filled with solder.

STEP 4: Cleanup the seam with steel-wool and a file. Make sure that there are no sharp edges to catch or cut the rope fibers when the fid is being used.

Making an Open Fid:

STEP 1: Enlarge the diagonal opening of the other piece of tubing by setting the tubing on end and forcing a rod into the opening. When the rod is forced into the opening, the cross section of the tubing should become "U" shaped.

STEP 2: With a round file, enlarge the diagonal opening to the shape shown by the dotted line.

STEP 3: Smooth all rough and sharp edges with a file and steel-wool.

STEP 4: Gently tap the edges of the opening toward each other so that a cross section anywhere along its entire length will be "U" shaped.

Making Handles For Fids:

STEP 1: Carve one end of a 1 inch diameter * 3 inch long piece of wood so that it will fit snugly into the end of the fid.

STEP 2: Attach handle to fid.

2A] Drill a small hole into the side of the fid about 1/2 inch from the end.

2B] Insert the handle into the end of the fid. Then drive a finishing nail through the hole into the wood of the handle.

2C] Cut the nail off close to the side of the fid. Then file the nail down so that it is smooth and even with the surface.

STEP 3: Finish the handle. Here is a chance to be creative. You can carve a simple rounded handle or let your imagination take over.

© 1999, Gerald L. Findley

JAPANESE SQUARE LASHINGS:

Comments —— The Japanese Square Lashings are a group of similar lashings that are all tied in a similar manner. The main difference is in the way each lashing is started.

The simplest and easiest form of the Japanese square lashing is tied by looping the center of the rope around the vertical spar and carrying the stands parallel to each other while taking the wrapping turns. The frapping turns are taken by separating the ends of the rope and taking them in opposite directions.

The MarkII Japanese Square Lashing is tied by looping the center of the rope of the upright spar and than forming the wrapping turns by taking the ends of the rope in opposite directions.

The Mark III is the same as the Mark II but a clove hitch is tied around the up right spar when starting the lashing.

The Mark III is the most secure of the three Japanese square lashings because the clove hitch helps to prevent the lashing from shifting along the vertical spar.

Narration -----(For **Japanese square lash** knotboard.) **(1)** Start the lashing by looping the center of the rope around the vertical spar so that the loops under the horizontal spar. **(2)** Start the wrapping turns by leading the ends around the spars so that the two strands of the rope are parallel to each other. **(3)** When making the wrapping turns the two strands of the rope are lead around the spars at 90^0 to the spars; do not allow the strand to cross, be sure to keep the strands parallel. **(4)** Complete the wrapping turns by leading the rope strand around the vertical pole. **(5)** Start the frapping turns by separating the strands so that one strand is above the horizontal spar and the other strand is below the horizontal spar. **(6)** Lead the frapping strands in opposite directions. **(7)** Make two complete frapping turns; pull each turn tight as it is made; tie the first half knot of the ending square knot. (8) Tie the second half knot of the square knot to complete the lashing. **(9)** For safety add half hitches; The half hitches prevent the square knot from upsetting.

© 1999, Gerald L. Findley

JAPANESE SQUARE LASHING

for safety add half hitches

© 1999, Gerald L. Findley

JAPANESE SQUARE LASHING MARK II

Narration ---(For **Japanese square lash, mark II** knotboard.) **(1)** Start the lashing by tying the center of the rope around the vertical spar with a clove hitch so that the clove hitch is under the horizontal spar. **(2)** Make the first wrapping turn by leading the ends up over the front of the horizontal spar and then in opposite directions behind the vertical spar. **(3)** Pull the strands tight but do not allow them to cross each other. **(4)** Add the second wrapping turn by leading the ends of the rope down over the front of the horizontal spar and then in opposite directions behind the vertical spar. **(5)** Complete the frapping turns by leading the ends of the rope up over the front of the horizontal spar and then in opposite directions behind the vertical spar. Position the strands of rope for starting the frapping tuns by leading them behind the horizontal spar. **[NOTE]** When pulled tight the strands will cross behind the vertical spar.

(6) Lead the frapping strands in opposite directions below and in front of the vertical spar and then behind the horizontal spar. **(7)** Make the second frapping turn by leading the ends above and in front of the vertical spar and then behind the horizontal spar; pull each turn tight as it is made. **(8) End** the second frapping turn by tying the firs half knot of the ending square knot. **(9)** Complete the ending square knot by adding a second half knot. **(10)** Pull the square knot tight **[NOTE]** For safety add half hitches around the horizontal spar to either side of the square knot; The half hitches prevent the square knot from upsetting.

MARLIN SPIKE HITCH:

Description —— A loop formed by a half hitch around a bight in the standing part of the rope.

Use —— To temporarily hold a toggle (a Marlin Spike) so that a rope can be pulled tight; as a mooring hitch that can be dropped over the end of a stake or pole; to hold the rungs of a rope ladder.

Comments —— A secure temporary hitch that can be easily spilled by removing the toggle. The Marlin Spike Hitch gets it name from the practice of using it around a Marlin Spike or similar tool to tighten knots and servicing,

Other Names —— Slip Noose; especially when the half hitch is pulled closed around the bight.

Narrative ---- (For **marlin spike** knotboard) **(1)** Form an overhand loop. **(2)** Then form a bight in the standing part. **(3)** Place the bight under the overhand loop. **(4)** Then reeve the bight through the underhand loop. **(5)** Pass a toggle through the eye of the bight **(6)** and pull tight.

6.

MARLIN SPIKE LADDER

SLIP NOOSE:

Description ----- An overhand knot tied around its standing part.

Use ---- As a sliding loop for a snare; as a toggled stopper knot.

Comments ---- Related to the overhand knot. Often confused with the slip knot.

Narrative ---- Tie by folding an overhand loop over the standing part and pulling a bight of the standing part through the eye of the overhand loop. (See marlin spike hitch.)

SLIP KNOT:

Description ----- An overhand knot tied around its running part.

Use ---- As a stopper knot.

Comments ---- Related to the overhand knot. Often confused with the slip noose.

Narrative ---- Tie by folding an overhand loop over the running part and pulling a bight of the running part through the eye of the overhand loop. (See marlin spike hitch.)

FOOTROPE KNOT

Description: a three strand knot that looks somewhat like a turk's head knot.
Comments: This knot was tied in the "footrope" (the rope that was tied under the yard arm for the sailors to stand on when they were setting the sails) to prevent the sailors' feet from slipping along the footrope.
Use: as a stopper knot in the end of a rope.

STEP 1: Unlay 4 to 5 turns of the lay.

STEP 2: Tie a loose crown knot.

STEP 3:

STEP 4:

STEP 5:

STEP 6:

STEP 7: Tie a wall knot under the crown knot but tuck the strands up through the center of the crown knot.

STEP 8:

STEP 9:

STEP 10:

STEP 11:

STEP 12:

STEP 13: Work tight and finish by combing out the fibers to form a tassel of relay the strand and whip the end of the rope.

© 1996, Gerald L. Findley

CAMP STOOL:

MATERIALS:

3 — 2 Foot * 2 inch poles
20 — 1/2 inch diameter sticks (various lengths)
1 — 3/8 inch * 5 foot rope
1 — 1/4 inch * 12 foot rope

CONSTRUCTION:

STEP 1: Cut a grove 1 inch deep and 3/8 inch wide in each end of the 2 foot poles. Be sure that the groves are in the same direction.

STEP 2: Lash the 2 foot pole together at their centers with the 1/4 inch * 12 foot rope. Use the **equal shear tripod lash** shown here.

2A] Tie a clove hitch around one of the poles; secure the end by wrapping it around the standing end.

2B] Take 4 wraps around the 3 poles; follow the pattern shown for each wrap.

2C] Take 2 frapping turns behind each pole.

2D] End the lashing with a clove hitch around one of the poles.

2E] Set the tripod up by rotating each leg.

STEP 3: Prepare the seat support rope by marking the middle of the 3/8 inch * 5 foot rope by tying a piece of twine around it. Then form a loop that has a 42 inch circumference by temporarily tying the ends of the rope together.

STEP 4: Place the seat support rope in the groves at the top of the poles so that the middle of the rope is in one of the groves. Adjust the ends poles so that they are evenly spaced around the loop.

STEP 5: Add the bracing rope. Tie a bowline into one end of the 1/4 inch * 10 foot rope. Then weave the rope back and forth between the ends of the tripod poles; follow the pattern shown in the diagram. End by tying a slippery half hitch through the eye of the bowline.

STEP 6: Assemble the seat.

6A] Lift one strand of the lay of the seat support rope on either side of the pole that is at the midpoint of the rope loop.

6B] Slide the ends of a 1/2 inch stick under the lifted strands of the seat support rope.

6C] Lift the next strand of the lay of the rope on either side of the pole that is at the midpoint of the seat support rope .

6C] Insert the next 1/2 inch stick**.**

© 1996, Gerald L. Findley

[NOTE] To keep the ends of the tripod poles at a equal distance from each other as the seat is being constructed, the temporary knot that joins the two ends of the seat support rope will need to be retied several times.

6E] Continue in this manner until the seat is the desired size.

6F] Permanently join the 2 ends of the rope loop with a short splice.

6G] Trim the ends of the 1/2 inch sticks so that they extend about 2 1/2 inches beyond the rope.

[NOTE] By removing the 1/4 inch brace rope, this stool can be folded for transport and storage.

[NOTES]

MONKEY'S PAW: COIL STYLE

Narration ---- (For **monkey's paw coil stile** knot-board.) **(1)** Form the first coil by stacking three loop on top of each other. **(2)** Insert core into center of coil. **(3)** Start second coil by forming a small loop at the bottom of the first coil. **(4)** Pass the running end behind and **(5)** across the front to for the first loop of the second coil. **(6)** Add the second and third loops of the second coil. **(7)** Start the third coil by reeving the running end through the top of the first coil and **(8)** then reeve the running end through the bottom of the first coil. **(9)** Add the second and third loops of the third coil. **(10)** Work all coils tight over the core.

[NOTE] Join the two ends of the monkey's paw with an eye splice, a short splice, or a seizing.

[NOTES}\]

Flag Pole Cleat:

A cleat is a device used to temporarily secure a line. When valuable equipment such as boat is being tied off, a commercially made cleat should be used. However, when a rustic appearance is desired a temporary cleat can be made with rope and wood.

Green Stick Cleat:

[Step 1] Round lash a piece of flexible green wood or a naturally curved piece of wood to the flag pole to make the horns of the cleat.

[Step 2] Tighten the round lashing by driving a small wedge on either side of the cleat.

[Step 3] Use frapping turns to raise the horns of the cleat.

Dry Wood Cleat:

Suggestion 1 ----

If only dry wood is available a cleat can be made as shown in the following diagrams:

[Step 1] Round lash a stick of suitable size to the flag pole to make the horns of the cleat.

[Step 2] Raise the horns by forcing short risers under each horn.

[Step 3] If needed tighten the round lashing by driving a small wedge on either side of the cleat.

Suggestion 2 ----

Preshape the cleat from a piece of limb wood .

[Step 1] Split a 3 inch diameter by 8 inch piece of limb wood in half.

[Step 2] Use an ax and knife to shape the horns on either end of split piece of wood.

[Step 3] Round lash the cleat to the flag pole.

© 1996, Gerald L. Findley

[Step 4] Tighten the round lashing by driving a small wedge on either side of the cleat.

Precut Cleats:

A cleat can be made from hard wood lumber by sawing it to the desired shape and then round lashed to the flag pole. Small wedges are used on either side of the cleat to tighten the round lashing and to stabilize the cleat.

Making Wedges:

[Step 1] Cut to size. Length --- slightly longer than the width of the round lashing. Diameter --- slightly larger than the gap formed between the rope, the flag pole, and the cleat.

[Step 2] Cut one end off at an angle.

[Step 3] Taper the sides of the point so that the point of the wedge is on one side.

ROPE WRENCH:

A rope wrench is a simple tool that can be used to tighten the ropes of a lashing. Use a crochet stick that is about 18 inches long and 1 1/2 inches in diameter; the crotch should be about 6 inches from the end.

Using A Rope Wrench:

[STEP 1] Use the rope wrench by placing it over the pole next to the rope that is to be tightened.

front view back view

[STEP 2] Wrap the rope around the fork of the wrench.

front view back view

STEP 3] Make one or two wraps around the handle of the wrench.

front view back view

[STEP 4] Grasp the handle so that you are holding the rope firmly to the handle; then rotate the wrench around the pole.

[NOTE] Tighten each turn of a lashing as it is made. The friction between the rope and the pole is too great to tighten more then one turn at a time.

Maintain the tightness of the rope by keeping a small amount of tension on it or by pressing the rope firmly against one of the poles while taking the next turn around the poles.

Be careful that the rope is not tightened so tight that the fibers of the rope begin to break.

NETTING:

The making of netting is an ancient craft. Many prehistoric cultures used netting for a verity of uses, storage bags, fencing, hammock, just to name some and of course the obvious use as a fish net. No matter what the netting was used for, the knitting of the mesh was done by tying a series of loops in some type of twine.

In one method, the basic knot used was the sheet bend. To form and tie the loops a knitting shuttle and a spacer (gauge) were used.

NETTING TOOLS:

The size of the shuttle and gauge that is needed will depend on the project that you are working on. The size of the shuttle and gauge given in the following directions is a convenient size for many projects and is also a good size to use for practicing the craft of netting. Shuttles and gauges of different sizes can be made by changing the size of the materials used.

Knitting Shuttle:

Make the knitting shuttle from a 1/4 inch * 1 inch * 12 inch piece of smooth grained hard wood. Carve and sand the shuttle to the shape shown in the diagram. Leave the shuttle unfinished; varnish or paint has a tendency to become sticky.

Knitting Gauge:

Make the knitting gauge from a 1/4 inch * 1 1/4 inch * 12 inch piece of smooth grained hard wood. Carve and sand the gauge to the shape shown in the diagram. Leave the gauge unfinished; varnish or paint has a tendency to become sticky.

Filling The Knitting Shuttle:

STEP 1: Fill the shuttle with twine. Start by tying a single hitch around the tongue of the shuttle and then pass the twine through the notch.

STEP 2: Turn the shuttle over, loop the twine around the tongue and then through the notch.

© 1996, Gerald L. Findley

STEP 3: Continue turning the shuttle from side and looping the twine around the tongue until the shuttle is filled.

[NOTE] To prevent synthetic twine from fraying, use a candle flame to cut and fuse the ends.

[WARNING] Using a butane cigarette lighter to cut or fuse synthetic rope or twine may cause the lighter to over heat and explode.

DIAMOND MESH NETTING:

Diamond mesh netting is the easiest of the two forms of mesh to make. Square mesh netting will be dealt with latter.

Casting On: To start diamond mesh netting the first row of mesh loops is cast on to a loop of some kind. The kind of loop used depends on the project; a ring, grommet, frame or loop of twine may be used. The following directions are for casting on to a ring but the same steps may be used for any starting loop.

STEP 1: Tie the end of the twine to the ring with a clove hitch stopped with two half hitches.

STEP 2: Place the twine behind the gauge then bring the twine in front of the gauge and to the right.

[NOTE]: The dotted circles in each of the diagrams is used to show the position of the thumb and finger of the left hand.

STEP 3: Reeve the twine through the ring from the front to the back so that an overhand loop is formed.

STEP 4: Pull the twine to the left to tighten the twine around the ring and the gauge.

STEP 5: Lay the twine across the ring from left to right.

STEP 6: Reeve the twine through the ring from the back to the front.

STEP 7: Place the twine behind the gauge; then pull the twine downward to tighten the twine around the ring. This forms a lark's head knot around the ring.

STEP 8: Repeat steps 2 through 7 for each additional loop required for the project.

KNITTING A ROW OF MESH:

Netting is made by knitting roes of mesh using a shuttle and a gauge. The gauge is used to determine the size of the mesh, and the shuttle is used to hold the twine and form and tie the mesh loops. The basic knot used in netting is the sheet bend. The following diagrams illustrate the tying of the sheet bend as it is used for knitting a net.

STEP 1: Bring the twine down and up the back of the gauge. Then pick up the next loop by passing the shuttle through the loop from front to back.

STEP 2: Pull the twine to the left to tighten the twine around the gauge. Use the thumb and finger of the left hand to hold the twine in place.

STEP 3: Lay a loop of twine over the loop just picked up.

© 1996, Gerald L. Findley

STEP 4: Pass the shuttle in back of the picked up loop and the through the loop that was laid on top.

STEP 5: Pull the twine downward and slightly to the right to tighten the knot.

STEP 6: Repeat steps 1 through 5 for each loop in the row.

STARTING A NEW ROW:

STEP 1: When the end of a row of mesh is reached, slide the accumulated loops off the gauge, turn the work piece over so that the running end of the twine is on the left side of the work piece.

STEP 2: Wrap the twine around the gauge from front to back; pick up the first loop by passing the shuttle through the loop from back to front.

STEP 3: Knit the loop in place by following the directions for knitting a row of mesh.

ADDING A LOOP:

For some projects it is necessary to increase the width of the netting part way through the project. The width of the netting is increased by adding loops of mesh.

A loop is added by picking up the same loop a second time so that two loops are formed in the new row of mesh are tied to the same loop in the previous row of mesh.

PROLONG KNOT

DESCRIPTION:

A flat knot that is made by interweaving two strands of rope.

USE:

As stair tread, mat, or chafing gear; also as a decorative knot in a two strand lanyard.

COMMENTS:

The prolong knot gets its name from the fact that it can be extended to any length.

TYING:

STEP 1:

Place the center of the rope over a peg or hook and tie a loose half knot.

STEP 2:

Extend the half knot as shown.

STEP 3:

Twist the left loop and extend it to the right side.

[NOTE] This will start the over under pattern of the weaving.

STEP 4:
Twist the right loop and extend it to the left side so that it is over the first extended loop.

STEP 5:
Weave the left strand to the right in the pattern shown.

STEP 6:
Weave the right strand to the left in the pattern shown.

[NOTE] This completes the four bight prolong knot. At this stage it may be ended and worked firm (over tightening distorts the knot) or the strands my be doubbled as shown in later diagrams.

STEP 7:
Twist the left loop and extend it to the right side.

STEP 8:
Twist the right loop and extend it to the left side so that it is over the first extended loop.

STEP 9:
Weave the right strand to the left in the pattern shown.

STEP 10:

Weave the left strand to the right in the pattern shown. This completes the 7 bight form of the prolong knot.

[NOTE] The prolong knot can be extended three bights at a time by repeating steps 7 through 10 for each extension.

STEP 11:

Start doubling the strands by chacing (following) the opposite strand.

STEP 12:

Complete doubling the strands. Then work the knot into a firm mat . Do not over tighten the strands as this will distort the mat.

[NOTE] The ends of the strands can be hidden by sewing them to the adjacent strand on the underside of the mat.

LIFE BASKET:

Description ---- A body harness made by combining a bowline on a bight and a french bowline.

Use ---- To lower a severally injured person when a life threatening situation exists.

Comments ---- The life basket is a secure harness that can be used to move an injured person that is weakened or unconscious. However, unless there is a life threatening situation, such as a burning building or immediate danger of avalanche, you should wait for a trained rescue team.

If you attempt to use the life basket, do not allow the rope to slide through your hands as you lower the injured person . The friction caused by the sliding rope can cause severe painful rope burns and loss of control of the rope. The rope must be let out in a hand over hand manner to insure a safe, controlled descent.

1.

Narration ---- (1) Tie a bowline on a bight. Place one loop of the bowline on a bight around each leg. [NOTE] (The bowline on a bight should be large enough so that when it is in place the knot should be close to the victims belt buckle. Be sure to leave the running part of the rope extending about 3 feet beyond the knot.)

2.

(2) Take a half hitch around the victims chest.

© 1996, Gerald L. Findley

(3) Form a bight in the standing part by pulling it under the right hand part of the half hitch so that an underhand loop is formed around the cross point of the half hitch.

(4) Fold the bight around and reeve it through the eye of the underhand loop.

(5) Reeve the running part of the rope through the bight.

(6) Take the slack out of the running part of the rope and fold the it over to form interlocking bights.

(7) Pull on the standing part so that the bight in the running part of the rope is pulled through the eye of the underhand loop and the underhand loop flips over and tightens around the bight to form a French Bowline.

SPHERICAL KNOB COVERING

This knot is used to cover knobs. One example would be to cover a knob at the end of a walking stick.

The length of cord needed to tie the knob covering knot depends on the size of the cord and the number of times the pattern is to be chased. A good length to start with is 8 times the circumference of the knob for each time the pattern is to be chased. [Example: a one inch knob has a circumference of a little over 3 inches. To cover a one inch knob it would require about 25 inches of cord for each time the pattern is chased. The pattern should be chased at least 2 times. This means that about 50 inches of cord would be used to cover a 1 inch knob.

The knob covering knot is difficult to tie “in hand” the easiest method of tying it is to make a copy of the diagram and fasten the diagram to a work board. Start by pinning the middle of the cord to the feathered end of the arrow in the diagram. Then following the path indicated, pin the cord to the diagram. Be sure to follow the over/under pattern indicated in the diagram. Studying the following partial diagrams may help.

After the knot is tied on the work board unpin it and work it loosely into shape over the knob. Then chase the pattern the required number of times. Next work the knot tight around the knob. Do not rush this stage. When the knot is tight cut off the ends of the cord and push the ends into the knot.

To preserve the knot, it may be varnished or painted.

Walking Stick:

Carve a knob on the end of the walking stick.

If desired, the size of the knob can be increased by wrapping it with tape.

Tie the covering knot and work it tight over the knob.

© 1999, Gerald L. Findley

CROWN KNOT:

Use ---- To tie of the end of a rope so that it does not unlay. ----- To begin a back splice. ---- As part of several multiple strand knots.

Narration ---- (For **crown knot** knotboard.) **(1)** Tie off the rope 6 complete lays from the end. **(2)** Unlay the rope to the tied off point. **(3)** Place the end of one of the unlayed strand between the other two unlayed strands; **(4)** press the strand firmly between the strands so that a loop is formed. **[NOTE]** As you are looking at the end of the rope work counterclockwise around the rope . **(5)** Fold the second strand over the first strand. **[NOTE]** This will hold the loop in the first strand in place. **(6)** Reeve the end of the third strand through the eye of the loop. **(7)** Fold the third strand over the second strand. **[NOTE]** This will hold the second strand in place. **(8)** Pull the loop closed. **[NOTE]** Work and pull all three strands until the knot is even and symmetrical.

CROWN KNOT

6.

7.

8.

pull all strands snug and even

[NOTE]

WALL KNOT

Use ---- To tie of the end of a rope so that it does not unlay. ---- As part of several multiple strand knots.

(1) Tie off the rope 6 complete lays from the end

(2) Unlay the rope to the tied off point.

NOTE: work the knot in a counterclockwise direction as you look at the end of the rope.

(3) Place the end of one of the unlayed strands under the strand to its left. (Hold the loop open as you work the knot).

(4) Place the second strand under the first and tthird strand.

(5) Placce the third strand under the second strand.

(6) Reeve the end of the third strand up through the loop formed in the first strand.

[A]

[B]

(7) work tight.

ALAMAR KNOT

The alamar knot is a decorative knot related to the pretzel. The pretzel knot is tied in a single strand; the alamar knot is tied by doubling the strands as showwn in [Step 1]

[Step 1] Double the strand as shown.

[Sterp 2]

[Sterp3]

[Step 4]

[Step 5] Add tassels or other end decorations.

The following topics about rope making are covered in :

ROPE WORKS

MATERIALS:

Any of the following materials may be used to make rope: binder twine, bailer twine, plastic twine, jute twine, yarn, string, or plastic bags. Just about any material that is made up of long flexible strands or that can be cut into strands can be used to make rope. However, only twines of proven strength should be used to make rope that will be expected to carry a load or lash a structure.

TYPE OF ROPE:

The type of rope that is explained in this book is three strand laid rope. This type of rope is made by twisting three strands of fiber in one direction and then laying the three strands together by allowing the strands to twist together in the opposite direction.

A SIMPLE ROPE MACHINE:

The twisting and laying can be done by hand but this takes a long time. To speed up the operation a machine is needed.

A rope machine consists of two devices; one that twists the three strands, the twisting end; and one that is used to lay the twisted strands together, the laying end.

ROPE WORKS has a set of diagrams showing a simple machine that can be made from scrap lumber and coat hanger wire.

SETTING UP A ROPE MACHINE:

After the two ends of the rope machine are positioned, tie the end of the twine to the laying end hook. Then hook the twine over one of the hooks on the twisting end, then back to the laying end hook. Continue back and forth until each of the three hooks on the twisting end have two lengths of twine on it. Be careful to keep the tension equal on all lengths of twine.

TWISTING THE STRANDS:

After the machine is set up, turn the cranks on the twisting end so that the cranks are turning clockwise as you are looking at the crank handles. It Is a good idea to mark this direction on the frame of the machine.

Twist the strands until they become firm and resist further twisting. If the strands are not twisted tight enough the rope will be loose. On the other hand if you twist the strands too tight the strands will kink. Kinked or loose strands will weaken the rope. Experience will teach you when the amount of twist is just right.

[NOTE] During the twisting the laying end must not be turned.

[NOTE] While twisting and laying a modest amount of tension must be kept on the rope.

LAYING THE ROPE:

To lay the rope a rope-wrench will be needed. A rope-wrench can be made from a crotched stick.

The actual laying of the rope is done by turning the laying end crank in a counterclockwise direction and moving the rope-wrench toward the twisting end.

MAKING A GEARED ROPE MACHINE:

A geared rope machine not only speeds up the process of making rope but can also be used to make rope several inches in diameter.

The patterns and instructions included in ROPEWORKS are for building a wooden geared rope machine that has a 3:1 gear ratio. This rope machine can be constructed with hand tools.

Lashing

Lashings are used to join poles or spars when building pioneering structures. These structures can be functional, such as tables, bridges, and towers or decorative such as gateways. The only limit as to the type of structure is the imagination of the builder.

Correctly tied lashings in pioneering structures are essential for safety. When young people see an interesting structure they charge up and over with no thought as to the soundness of the structure. This places the responsibility for a safe structure directly on the builder.

The following topics about lashing are covered in :

Splicing

Splicing is used to join ropes together by interweaving the strands of the rope. Splicing is the safest way to fasten two ropes together or to form a loop. Knots could also be used to do these jobs but knots weaken the rope by as much as 30 to 55 percent of the original strength of the rope. However, with a splice the rope is 85 to 90 percent as strong as the original rope. Splicing should be used whenever there is a concern about safety or when the loop or joint is going to be left in the rope.

[NOTE] After a splice is started or after each round of tucks, fold the strands back over the work. You will notice that there is one strand going in and one strand coming out between each of the strands of the standing end. If this configuration does not exist you have made a mistake; trace the strands back and correct the mistake or pull strands out and start over.

Knots

The use of rope in the workplace was common practice until the midpoint of this century. At that time, modern materials handling techniques started to be used and the use of ropes declined. Along with this decline in the use of ropes in the work place there was also a decline in the knowledge of how to use rope safely.

The more common uses of rope by the average person is the securing of a load to a personal vehicle or for recreational purposes. Both of these uses require a knowledge of how to choose and tie safe, secure knots. If this knowledge is not available, the consequences can be devastating, resulting in personal injury or the loss of personal equipment.

For the last 35 years I have been learning and teaching about rope. My experience in teaching about rope has shown me that most people must be shown how to tie a knot in small, sequential steps, and they must be shown many times before they can tie a knot with confidence.

In preparing this book I have attempted to design a set of teaching aids that present each selected knot, splice, or lashing in small, sequential steps. These teaching aids enable the learner to study each step and to duplicate it with a length of practice rope.

The knots, splices and lashings presented in this book were selected because of their use by the Boy Scouts of America and others who are interested in outdoor recreation.

The following knots and hitches are covered in :

ROPE WORKS ©1996 Gerald L. Findley, all rights reserved

INTRODUCTION

ROPE WORKS is a book that evolved to meet the needs of Scouts and Scouters. R0PE WORKS' 97 pages are bound in a plastic comb binding that allows it to lay flat while in use. Its 6 inch by 8 1/2 inch size makes it convenient to carry as a reference source. ROPE WORKS provides detailed step by step illustrations in a knot board layout. The knot board layout clearly shows each step required to tie a knot. The detailed steps allows the user of ROPE WORKS to learn the art of **knot tying**, **splicing**, and **lashing** without the constant supervision of an instructor. The table of contents, glossary of terms and complete index will help you find and tie the knots you need.

Twenty-two pages of ROPE WORKS are devoted to **rope making** and the building of a **geared rope machine.**

View our sample illustrations to see what we are talking about. Then order your copy of Rope Works today by using the handy mail in **order form** found at our Ordering Information button.

KNOT SAFETY

If a knot is improperly tied or a wrong knot is used, an unsafe condition is created. Therefore it is not just enough for the teacher to teach someone how to tie a knot correctly, but it is also necessary to teach them how to use the knot correctly. Likewise it is the student's responsibility to learn how to correctly tie and use the knot. If either the teacher or the student does not accept their responsibility they are endangering themselves and others.

The most commonly used rope is right hand-lay rope; that is as you are looking at the rope, it appears to twist to the right and away from you. Because of the right-hand lay of most rope, the majority of knots hold best when tied in a right hand manner. If the knot is tied in a left-hand manner or the mirror image of its usual form, the knot may fail because the right-hand twist of the rope may cause the knot to loosen or spill more easily. This is especially true if the tension on the rope is repeatedly changed.

Thanks and safe tying.

Manage & Analyze your Web Site Traffic with FastCounter Pro

Monitor the effectiveness of your Web site in real-time

Make sure your Web site is working for you! FastCounter Pro is our easy to use and affordable traffic analysis service that allows you to monitor your Web site traffic. Use this information to your advantage and improve the design and efficiency of your Web site. FastCounter Pro allows you to:

- Monitor the success of your Web site in real-time
- Measure the ROI of your advertising campaigns
- Track your conversions to see how valuable your traffic is
- Find out which referrer sends you the most sales
- See which keyword phrases are being used in search engines to find your site
- Collect data about the operating systems and browsers of your visitors
- Get online support 24x7

Check out our live demo of FastCounter Pro!

Rope

From Wikipedia, the free encyclopedia

A **rope** is a group of yarns, plies, or strands that are twisted or braided together into a larger and stronger form. Ropes have tensile strength and so can be used for dragging and lifting, but are too flexible to provide compressive strength. As a result, they cannot be used for pushing or similar compressive applications. Rope is thicker and stronger than similarly constructed cord, line, string, and twine. Fiber rope is made from fiber, whereas wire rope is made from wire.

Construction

Rope may be constructed of any long, stringy, fibrous material, but generally is constructed of certain natural or synthetic fibres. Synthetic fibre ropes are significantly stronger than their natural fibre counterparts, but also possess certain disadvantages, including slipperiness.

Common natural fibres for rope are manila hemp, hemp, feathers, linen, cotton, coir, jute, straw, and sisal. Synthetic fibres in use for rope-making include polypropylene, nylon, polyesters (e.g. PET, LCP, Vectran),

polyethylene (e.g. Dyneema and Spectra), Aramids (e.g. Twaron, Technora and Kevlar) and acrylics (e.g. Dralon). Some ropes are constructed of mixtures of several fibres or use co-polymer fibres. Wire rope is made of steel or other metal alloys. Ropes have been constructed of other fibrous materials such as silk, wool, and hair, but such ropes are not generally available. Rayon is a regenerated fibre used to make decorative rope.

Three-strand twisted natural fiber rope

The twist of the strands in a twisted or braided rope serves not only to keep a rope together, but enables the rope to more evenly distribute tension among the individual strands. Without any twist in the rope, the shortest strand(s) would always be supporting a much higher proportion of the total load.

Usage

Rope is of paramount importance in fields as diverse as construction, seafaring, exploration, sports, theatre, and communications; and has been used since prehistoric times. To fasten rope, many types of knots have been invented for countless uses.[1] Pulleys redirect the pulling force to another direction, and can create mechanical advantage so that multiple strands of rope share a load and multiply the force applied to the end. Winches and capstans are machines designed to pull ropes.

Mooring and rope

Rock climbing ropes

The modern sport of rock climbing uses so-called "dynamic" rope, which stretches under load in an elastic manner to absorb the energy required to arrest a person in free fall without generating forces high enough to injure them. Such ropes normally use a kernmantle construction, as described below. "Static" ropes, used for example in caving, rappelling, and rescue applications, are designed for minimal stretch; they are not designed to arrest free falls. The UIAA, in concert with the CEN, sets climbing-rope standards and oversees testing. Any rope bearing a GUIANA or CE certification tag is suitable for climbing. Despite the hundreds of thousands of falls climbers suffer every year, there are few recorded instances of a climbing rope breaking in a fall; the cases that do are often attributable to previous damage to, or contamination of, the rope. Climbing ropes, however, do cut easily when under load. Keeping them away from sharp rock edges is imperative.

Dynamic Kernmantle rock climbing rope with its braided sheath cut to expose the twisted core yarns and core yarn plies.

Rock climbing ropes come with either a designation for single, double or twin use. A single rope is the most common and it is intended to be used by itself, as a single strand. Single ropes range in thickness from roughly 9mm to 11mm. Smaller ropes are lighter, but wear out faster. Double ropes are thinner ropes, usually 9mm and under, and are intended for use as a pair. These ropes offer a greater margin or security against cutting, since it is unlikely that both ropes will be cut, but they complicate belaying and leading. Double ropes are usually reserved for ice and mixed climbing, where there is need for two ropes to rappel or abseil. They are

also popular among traditional climbers, and particularly in the UK, due to the ability to clip each rope into alternating pieces of protection; allowing the ropes to stay straighter and hence reduce rope drag. Twin ropes are not to be confused with doubles. When using twin ropes, both ropes are clipped into the same piece of protection, treating the two as a single strand. This would be favourable in a situation where there was a high chance of a rope being cut. However new lighter-weight ropes with greater safety have virtually replaced this type of rope.

Section through the same rope

The butterfly coil is a method of carrying a rope used by climbers where the rope remains attached to the climber and ready to be uncoiled at short notice. Another method of carrying a rope is the alpine coil.

Aerial rope

Rope is also an aerial acrobatics circus skill, where a performer makes artistic figures on a vertical suspended rope. Tricks performed on the rope are, for example, drops, rolls and hangs.They must also be strong [2] *See also Corde lisse*.

History

The use of ropes for hunting, pulling, fastening, attaching, carrying, lifting, and climbing dates back to prehistoric times. It is likely that the earliest "ropes" were naturally occurring lengths of plant fibre, such as vines, followed soon by the first attempts at twisting and braiding these strands together to form the first proper ropes in the modern sense of the word. Impressions of cordage found on fired clay provide evidence of string and rope-making technology in Europe dating back 28,000 years.[3] Fossilized fragments of "probably two-ply laid rope of about 7 mm diameter" were found in one of the caves at Lascaux, dating to approximately 15,000 BC.[4]

Ancient Egyptians were the first to document tools for ropemaking

The ancient Egyptians were probably the first civilization to develop special tools to make rope. Egyptian rope dates back to 4000 to 3500 B.C. and was generally made of water reed fibres.[5] Other rope in antiquity was made from the fibres of date palms, flax, grass, papyrus, leather, or animal hair. The use of such ropes pulled by thousands of workers allowed the Egyptians to move the heavy stones required to build their monuments. Starting from approximately 2800 B.C., rope made of hemp fibres was in use in China. Rope and the craft of rope making spread throughout Asia, India, and Europe over the next several thousand years.

In the Middle Ages (from the 13th to the 18th centuries), from the British Isles to Italy, ropes were constructed in ropewalks, very long buildings where strands the full length of the rope were spread out and then *laid up* or twisted together to form the rope. The cable length was thus set by the length of the available rope walk. This is related to the unit of length termed *cable length*. This allowed for long ropes of up to 300 yards long or longer to be made. These long ropes were necessary in shipping as short ropes would require splicing to make them long enough to use for sheets and halyards. The strongest form of splicing is the short splice, which doubles the cross-sectional area of the rope at the area of the splice, which would cause problems in running the line through pulleys. Any splices narrow enough to maintain smooth running would be less able to support

the required weight.

Leonardo da Vinci drew sketches of a concept for a ropemaking machine, but it was never built. Nevertheless, remarkable feats of construction were accomplished without advanced technology: In 1586, Domenico Fontana erected the 327 ton obelisk on Rome's Saint Peter's Square with a concerted effort of 900 men, 75 horses, and countless pulleys and meters of rope. By the late 18th century several working machines had been built and patented.

Some rope is still made from natural fibres, such as coir and sisal, despite the dominance of synthetic fibres such as nylon and polypropylene, which have become increasingly popular since the 1950s.

Styles of rope construction

Laid or twisted rope

Illustration of the S and Z naming convention

Laid rope, also called twisted rope, is historically the prevalent form of rope, at least in modern western history. Common twisted rope generally consists of three strands and is normally right-laid, or given a final right-handed twist. The ISO 2 standard uses the uppercase letters **S** and **Z** to indicate the two possible directions of twist, as suggested by the direction of slant of the central portions of these two letters. The handedness of the twist is the direction of the twists as they progress away from an observer. Thus Z-twist rope is said to be right-handed, and S-twist to be left-handed.

Twisted ropes are built up in three steps. First, fibres are gathered and spun into yarns. A number of these yarns are then formed into strands by twisting. The strands are then twisted together to lay the rope. The twist of the yarn is opposite to that of the strand, and that in turn is opposite to that of the rope. It is this counter-twist, introduced with each successive operation, which holds the final rope together as a stable, unified object.[6]

Traditionally, a three strand laid rope is called a *plain-* or *hawser-laid*, a four strand rope is called *shroud-laid*, and a larger rope formed by counter-twisting three or more multi-strand ropes together is called *cable-laid*.[7]

Rope making using the twisted rope method on a 1928 Metters Rope Making Machine

One property of laid rope is partial untwisting when used. This can cause spinning of suspended loads, or stretching, kinking, or hockling of the rope itself. An additional drawback of twisted construction is that every fibre is exposed to abrasion numerous times along the length of the rope. This means that the rope can degrade to numerous inch-long fibre fragments, which is not easily detected visually.

Twisted ropes have a preferred direction for coiling. Normal right-laid rope should be coiled clockwise, to prevent kinking. Coiling this way

imparts a twist to the rope. Rope of this type must be bound at its ends by some means to prevent untwisting.

Braided rope

While rope may be made from three or more strands,[8] modern braided rope consists of a braided (tubular) jacket over strands of fiber (these may also be braided). Some forms of braided rope with untwisted cores have a particular advantage; they do not impart an additional twisting force when they are stressed. The lack of added twisting forces is an advantage when a load is freely suspended, as when a rope is used for rappelling or to suspend an arborist. Other specialized cores reduce the shock from arresting a fall when used as a part of a personal or group safety system.

A rope braiding machine at the Arbetets Museum (Museum of Work) in Norrköping, Sweden

Braided ropes are generally made from nylon, polyester, polypropylene or high performance fibers such as high modulus polyethylene (HMPE) and aramid. Nylon is chosen for its strength and elastic stretch properties. However, nylon absorbs water and is 10-15% weaker when wet. Polyester is about 90% as strong as nylon but stretches less under load and is not affected by water. It has somewhat better UV resistance, and is more abrasion resistant. Polypropylene is preferred for low cost and light weight (it floats on water) but it has limited resistance to ultraviolet light, is susceptible to friction and has a poor heat resistance.[9][10][11][12]

Braided ropes (and objects like garden hoses, fibre optic or coaxial cables, etc.) that have no *lay* (or inherent twist) uncoil better if each alternate loop is twisted in the opposite direction, such as in figure-eight coils, where the twist reverses regularly and essentially cancels out.

Single braid consists of an even number of strands, eight or twelve being typical, braided into a circular pattern with half of the strands going clockwise and the other half going anticlockwise. The strands can interlock with either twill or plain weave. The central void may be large or small; in the former case the term **hollow braid** is sometimes preferred.

Double braid, also called **braid on braid**, consists of an inner braid filling the central void in an outer braid, that may be of the same or different material. Often the inner braid fibre is chosen for strength while the outer braid fibre is chosen for abrasion resistance.

In **solid braid** the strands all travel the same direction, clockwise or anticlockwise, and alternate between forming the outside of the rope and the interior of the rope. This construction is popular for general purpose utility rope but rare in specialized high performance line.

Kernmantle rope has a core (kern) of long twisted fibres in the center, with a braided outer sheath or mantle of woven fibres. The kern provides most of the strength (about 70%), while the mantle protects the kern and determines the handling properties of the rope (how easy it is to hold, to tie knots in, and so on). In dynamic climbing line, core fibres are usually twisted, and chopped into shorter lengths, which makes the rope more elastic. Static kernmantle ropes are made with untwisted core fibres and tighter braid, which causes them to be stiffer in addition to limiting the stretch.

Other types

Plaited rope is made by braiding twisted strands, and is also called *square braid*. It is not as round as twisted

rope and coarser to the touch. It is less prone to kinking than twisted rope and, depending on the material, very flexible and therefore easy to handle and knot. This construction exposes all fibres as well, with the same drawbacks as described above. **Brait rope** is a combination of braided and plaited, a non-rotating alternative to laid three-strand ropes. Due to its excellent energy-absorption characteristics, it is often used by arborists. It is also a popular rope for anchoring and can be used as mooring warps. This type of construction was pioneered by Yale Cordage.

Endless winding rope is made by winding single strands of high-performance yarns around two end terminations until the desired break strength or stiffness has been reached. This type of rope (often specified as cable to make the difference between a braided or twined construction) has the advantage of having no construction stretch as is the case with above constructions. Endless winding is pioneered by SmartRigging and FibreMax.

Safe and proper rope handling

Rope made from hemp, cotton or nylon is generally stored in a cool dry place for proper storage. To prevent kinking it is usually coiled. To prevent fraying or unravelling, the ends of a rope are bound with twine (whipping), tape, or heat shrink tubing. The ends of plastic fibre ropes are often melted and fused solid; however, the rope and knotting expert Geoffrey Budworth warns against this practice thus:[13]

> *Sealing rope ends this way is lazy and dangerous.* A tugboat operator once sliced the palm of his hand open down to the sinews after the hardened (and obviously *sharp*) end of a rope that had been heat-sealed pulled through his grasp. There is no substitute for a properly made whipping.

Cordage aboard the French training ship *Mutin*

If a load-bearing rope gets a sharp or sudden jolt or the rope shows signs of deteriorating, it is recommended that the rope be replaced immediately and should be discarded or only used for non-load-bearing tasks.[14][15]

The average rope life-span is 5 years. Serious inspection should be given to line after that point. However, the use to which a rope is put affects frequency of inspection. Rope used in mission-critical applications, such as mooring lines or running rigging, should be regularly inspected on a much shorter timescale than this, and rope used in life-critical applications such as mountain climbing should be inspected on a far more frequent basis, up to and including before each use.

When preparing for a climb, it is important to stack the rope on the ground or a tarp and check for any "dead-

spots".

Avoid stepping on rope, as this might force tiny pieces of rock through the sheath, which can eventually deteriorate the core of the rope. Ropes may be flemished into coils on deck for safety and presentation/tidiness as shown in the picture.

Many kinds of filaments in ropes are weakened by acids or other corrosive liquids or solvents, and high temperatures. Such damage is treacherous because it often is hard to tell by eye.[16] Rope damaged in such ways is dangerous to use. Ropes therefore should be kept away from all kinds of solvents and from corrosive acids, alkalis, and oxidising agents.[17]

In addition, ropes should avoid sudden load, as a shock load can destroy a rope easily.[18] Any operation of ropes should obey the principle of safe working load, which is usually much less than its ultimate strength. The rope should be replaced immediately if any evidences of shock load have been found.

A rope under tension — particularly if it has a great deal of elasticity — can be very hazardous if it should part, snapping backward and potentially causing grave or lethal injury to people, or damage to objects, in its path. There are occasions when it is proper to cut a taut rope under load, but this should be done *only* when necessary and *only* with great forethought and preparation for the potential consequences.

Line

"Rope" refers to the manufactured material. Once rope is purposely sized, cut, spliced, or simply assigned a function, the result is referred to as a "line", especially in nautical usage. Sail control lines are mainly referred to as sheets (e.g. jibsheet). A halyard, for example, is a line used to raise and lower a sail, and is typically made of a length of rope with a shackle attached at one end. Other examples include clothesline, chalk line, anchor line ("rode"), stern line, fishing line, marline and so on.

~ SSRsi's Rope & Net Making Page ~
We tend to take alot of things for granted in the modern world. Ropes - from twine to cables - and nets are a couple of them. But when you can't visit the local hardware store for more, you'd better know how to make some cordage yourself! .

Miscellaneous

KNOTS: A knowledge of knots has saved many a life in storm and wreck, and if everyone knew how to tie a knot quickly and securely there would be fewer casualties in hotel and similar fires where a false knot in the fire escape rope has slipped at the critical moment and plunged the victim to the ground. Many an accident has occurred through a knot or splice being improperly formed. Even in tying or roping a trunk, few people tie a knot that is secure and quickly made and yet readily undone.

Knots & Hitches Part I Basics By Jaden, 17 July 2003. Knowing how to tie some very easy and basic knots and hitches might just come in very handy someday. I've used 2 different color ropes to help enhance the detail.

Nets & Net Making Forum discuss fancy knots and especially pineapple knots! ...a place to find those hard-to-find knot tying tools, cords, hardware, etc. ...a place to sell your knots and display your work! ***Link fixed, 09/14/08 - sorry 'bout that.***

La Riata - The Lariat. ~ Making & Throwing the Lariat Excerpt from the: "The Outdoor Handy Book ... for Playground, Field & Forest" By D.C. Beard, 1914; Chapter XXXIII: Properly speaking, there is no such thing as a "lasso." You may lasso things with la riata, but you cannot carry a "lasso," because lasso is a verb, and no cow-boy carries a verb coiled at his saddle-bow though he may have strings of forcible adjectives under his tongue...

Some animated knots

Cordage

Some plants used for cordage:

- Agave (Agavaceae) dead leaves cut, beaten.
- Basswood (Tilia americana) inner bark peeled and retted.
- Bull Thistle twist together the tough fibers of the stalk
- Cedar (Cupressaceae)bark
- Cattail (Typha) leaves, shredded
- Cedar pull strips of bark off trunk
- Cottonwood Shred the inner bark for fibers
- Dogbane or Indian Hemp(Apocynaceae) root, bark, inner fiber, or vines, with leaves removed, pounded
- Day Lily (Hemerocallis) leaves dryed, soaked, mellowed.
- Elm Bark (Ulmus americana) inner bark.
- Flax (Linum Usitatissimum) bast fiber, retted and scutched.
- Hickory Shred the inner bark for fibers
- Iris (Iridaceae) leaves, harvest green or browned, dried, soaked, mellowed.
- Juniper Fiber may be obtained from roots and inner bark
- Linden Shred the inner bark for fibers
- Milkweed (Asclepiadaceae) stem fiber or decayed stem fiber, bark.
- Mulberry Shred the inner bark for fibers
- Nettles (Laportea canadensis)stem fiber
- Red Osier Dogwood (Cornaceae) bark
- Sagebrush (Asteraceae) bark
- Sedge (Cyperaceae) roots, leaves

Making Traditional Cordage in North America, by Ron: This article is about cordage, one of the most used and necessary items for day-to-day life. Other than sinew, catgut, and rawhide, early man made his rope and string from more readily available plant material. Certain plant fibers were able to stand up to water emersion and made excellent nets and fishing line. Animal fibers, such as sinew and catgut, would stretch or unravel when wet and were more difficult to procure. Plant fibers were so much more abundant and easier to process; this left sinew and catgut for sewing, bow backing, arrow making and other arts requiring a strong, longer lasting material. **Article (all text) also has a much longer list of North American plants used for making cordage.**

Cordage Fiber Shredder Made From Bone by Dick Baugh: This little device arose from two situations. I had some left over bone pieces from a knife handle project and I use a lot of cattail leaves for cordage in grade school projects. Cattail leaf cordage is stronger and more flexible when it is finely shredded. In the past I have shown students how to shred the leaves by pulling them apart by hand while holding the base of the leaf with their feet. The ultimate way to shred the leaves is with a florists frog but that isn't very aboriginal...

Making Cordage By Hand by Norm Kidder: Cordage (rope and string) can be made from many different fibers including (Bast) Dogbane, Milkweed, Nettles, Hemp, Flax; (Leaves) Cattail, Yucca, Agave, Douglas Iris; (Bark) Willow, Maple, Basswood, Cedar; (Root) Leather Root, Beach Lupine; (Whole stem) Tule, straw, Juncus. Each material has specific requirements for extracting and preparing the fibers, but there are only two basic ways for using the fibers to make a cord: braiding (or plaiting) and twining. Braiding was usually done with flat, split materials such as cattail or flattened straw...

Probably the best Cordage site on the net. Includes a variety of materials, an .avi to view making cordage, an animated gif, and some links! Courtesy of NativeTech. Good work, folks!

Making Cordage ~ Once the plant and sinew fibers had been prepared, the making of cordage could actually be done. There are two methods for making the fibers into cordage... Learn About Finger Twining | Learn About Leg Rolling Method | Learn About Splicing

Cordage, or twine, was made in a variety of ways and from a variety of materials. For my experiment with cattail mats, nettle and basswood were used to make cordage. Milkweed, dogbane, slippery elm bark, cedar bark strips, shredded cattail, sinew, hide, and many other fibrous materials can also be used to make cordage.

EXPERIMENTAL ARCHAEOLOGY: MAKING CORDAGE ~ In this lesson students will become experimental archaeologists and make cordage from native plant fibers or craft items. Cordage artifacts are seldom found in North Carolina sites because the region's wet, humid climate and acidic soils cause them to decay. However, cordage was an important part of earlier tribes' technology, and indirect evidence exists for how people used it.

MAKING NATURAL CORDAGE [Mother Earth News] Cordage — that is, thread, string, or rope — is all but indispensable in a survival situation. It can be used for (among other things) bowstrings, fishing lines, trap triggers, snares, and lashings. Most people would likely despair if forced to make their own rope or string. However, the materials needed to do so are plentiful in most places (you'll find a list of possible options accompanying this article), and the techniques required are actually quite simple to master. Cordage is the term used for any type of rope or string made by twisting fibers together. This was an invaluable tool for Native Americans and it had a major impact on their daily lives. The manufacturing of cordage by Native Americans has changed very little over the many years of its use.

Skill: Making Yucca Cordage: Cordage (rope, string, etc.) is a very useful thing to have in a survival situation. You can use it for making shelter, snares, bowstrings, tools for making fire and bundling things together just to name a few things. The yucca plant is one of the best plants for making cordage. Here are three reasons why...

Making Cordage From Natural Fibers ~ Adapted from Participating in Nature: Thomas J. Elpel's Field Guide to Primitive Living Skills: Cordage, or string, is one of those simple little things which we seldom think about but use every day and take for granted. It is only when we need a piece of cordage and do not have any that we begin to notice just how handy it is. In primitive living cordage is an integral part of many other skills. Primitive peoples used cordage for such diverse projects as fish nets and fishing line, rabbit nets, hammocks, bow and bowdrill strings, woven bags, trap strings and snares, lashing, sewing, and for just tying things up.

Making Cordage by Scott Stoddard (American Survival Guide) March 1995: In the hierarchy of tools, rope and cordage must be near the top. A good knife is probably more important, as well as flint and steel for starting fires, but cordage has got to be right up there. It can hunt for you, help shelter you, and with sufficient strength, cordage can even save your life.

Cordage Plants Twig bark is available year-round, but fall is the time to harvest the stems of fibrous plants for making cordage, otherwise known as string.

How to Make Cordage Once you have collected stalks of milkweed or dogbane, or twigs of basswood or elm, you must detach the bark, since the fibrous inner bark will be used to make string.

Native American Cordage Technology Here is a wonderful summary article on how to produce cordage by using authentic Native American Techniques. A list of possible cordage plants is included.

Netting

Pomo Netting (As learned from Craig Bates) by Norm Kidder

Fishing For Change Pretty good article on net usage followed by small segment on net making and patching.

Basic Netmaking, How To Make Nets

Netting: Concepts in Shaping a Net: Once you learn how to make a basic knot for netting, making your net the shape you want it becomes the next big challenge. It is especially confusing since in most cases you will be making the net as a series of diamonds, but want the end result to be viewed as squares. To gradually get used to the concept, we will first work on shapes that stay diamonds (like tubular netting) and then learn how to form flat shapes.

NETTING: The making of netting is an ancient craft. Many prehistoric cultures used netting for a verity of uses, storage bags, fencing, hammock, just to name some and of course the obvious use as a fish net. No matter what the netting was used for, the knitting of the mesh was done by tying a series of loops in some type of twine.

A Heavenly Hammock [Mother Earth News] There are few experiences more restful than relaxing on a summer's afternoon — while the sun bakes well-being into your soul — in the cradling arms of a good hammock. Of course, the swinging lounges can be very expensive ... but if you can scrounge some 10 to 20 hours of work time and about $20 for materials, you might well be able to tie a netted slumber nest of your own. Here's how.
